In our hunter-gatherer ancestral environment, two parents were better than one. Attachment bonds between procreative partners would have greatly enhanced the survival of their offspring (Zeifman & Hazan, 2000).

Bowlby (1969) identified three basic behavioural systems that bond male–female pairs together: attachment, caregiving and sex. Shaver *et al.* (1996) have proposed a theory of adult romantic love in terms of these three systems. So, when we say 'I love you', we can mean any or all of the following.

- *Love as attachment:* 'I am emotionally dependent on you for happiness, safety and security; I feel anxious and lonely when you're gone, relieved and stronger when you're near. I want to be comforted, supported emotionally, and taken care of by you ...'
- *Love as caregiving:* 'I get great pleasure from supporting, caring for and taking care of you; from facilitating your progress, health, growth and happiness ...'

Table 28.1 The four stages of adult attachment in relation to Bowlby's four phases of infant attachment development

Bowlby's phases of infant attachment	Pre-attachment (0–3/4 months)	Attachment-in-the-making (3/4–6/7 months)	Clear-cut attachment (6/7–12/18 months)	Goal-directed partnership (12–18 months onwards)
Four stages of adult attachment	Attraction and flirting	Falling in love	Loving	Life as usual

Based on Zeifman & Hazan (2000)

- *Love as sexual attraction:* 'I am sexually attracted to you and can't get you out of my mind. You excite me, "turn me on", make me feel alive … I want to see you, devour you, touch you, merge with you, lose myself in you, "get off on you" …'

Zeifman & Hazan (2000) believe that there are four stages of adult attachment that mirror Bowlby's (1969) four phases of infants' attachment to the mother(-figure). These are summarised in Table 28.1 (page 476).

STAGE THEORIES OF RELATIONSHIPS

> *ASK YOURSELF…*
> - Do you think there are any 'natural' stages that all intimate (romantic and non-romantic) relationships go through (assuming the 'romantic' ones last a reasonable amount of time – so one-night-stands don't count!).

Our own experience tells us that intimate relationships change and develop over time. Indeed, those which stagnate ('we're not going anywhere'), especially sexual/romantic relationships, may well be doomed to failure (Duck, 1988).

The filter model (Kerckhoff & Davis, 1962)

Kerckhoff and Davis compared 'short-term couples' (together for less than 18 months) with 'long-term couples' (18 months or more) over a seven-month period. According to their *filter model:*

- *similarity of sociological* (or *demographic*) *variables* determines the likelihood of individuals meeting in the first place. To some extent, our choice of friends and partners is made for us; social circumstances reduce the '*field of availables*' (Kerckhoff, 1974) – that is, the range of people that are *realistically* available for us to meet (as opposed to those who are theoretically available). There's considerable *preselection* of the types of people we come into contact with, namely those from our own ethnic, racial, religious, social class and educational groups; these are the types of people we tend to find most attractive initially, since similarity makes communication easier and we've something immediately in common with them, as a group. At this point, attraction has little to do with other people's individual characteristics (this is the first 'filter')
- the next filter involves the psychological characteristics of individuals, specifically *agreement on basic values.* This was found to be the best predictor of the relationship becoming more stable and permanent; those who'd been together for less than 18 months tended to have a stronger relationship when the partners' values coincided
- but with the long-term couples, similarity wasn't the most important factor. The best predictor of a longer-term commitment was *complementarity of emotional needs* (this constitutes the third filter).

Stimulus–value–role theory (Murstein, 1976, 1986, 1987)

According to Murstein's *stimulus-value-role* (SVR) *theory,* intimate relationships proceed from:

- a *stimulus stage,* in which attraction is based on external attributes (such as physical appearance), through
- a *value stage,* in which similarity of values and beliefs becomes much more important, and finally to
- a *role stage,* which involves a commitment based on successful performance of relationship roles, such as husband and wife.

Although all three factors have some influence throughout a relationship, each one assumes greatest significance during one particular stage.

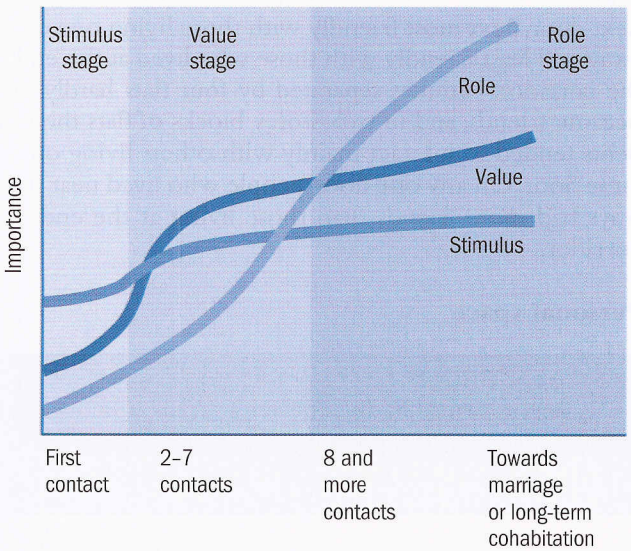

Figure 28.2 States of courtship in SVR theory (Murstein, 1987, based on Brehm, 1992)

An evaluation of stage theories

Brehm (1992) points out that many studies have provided only weak evidence for a fixed sequence of stages in intimate relationships. 'Stages' are probably best regarded as 'phases' that take place at different times for different couples. However, the claim that relationships change and develop isn't in dispute, and it's useful to think of this as involving a beginning, a middle and an end, corresponding to the three questions that were posed at the beginning of the chapter (see *Introduction and overview*). For example, how each partner understands the role of husband and wife, and how well each performs their role, are relatively late influences in a given courtship. The matching of partners' role concepts will be irrelevant to the success of the early stages of the courtship (Duck, 1999).

INTERPERSONAL ATTRACTION: HOW RELATIONSHIPS GET STARTED

A general theoretical framework for explaining initial attraction is that we're attracted to individuals whose presence is *rewarding* for us (e.g. Clore & Byrne, 1974; Lott & Lott, 1974). The more rewards someone provides for us, the more we should be attracted to that individual. A number of factors have been found to influence initial attraction through their reward value, including *proximity, exposure* and *familiarity, physical attractiveness,* and *similarity.*

Proximity, exposure and familiarity

Proximity

Proximity (physical or geographical closeness) represents a minimum requirement for attraction, because the further apart two people live, the lower the probability that they'll ever meet, let alone become friends or marry each other. Festinger *et al.* (1950) studied friendship patterns in a university campus housing complex for married students. People were more friendly with those who lived next door, next most friendly with those living two doors away, and least friendly with those who lived at the end of the corridor. Families separated by four flats hardly ever became friends, and in two-storey blocks of flats the residents tended to interact mainly with others living on the same floor. On any one floor, people who lived near stairways had more friends than those living at the end of a corridor.

Personal space

ASK YOURSELF...

- If you're sitting in an otherwise empty row of seats in a train and someone comes and sits right next to you, how do you think you'd react, and why?

In a series of studies by Sommer, the experimenter deliberately sat close to unsuspecting people when there was plenty of other available space, in order to see how likely they were to react to this invasion of their personal space.

KEY STUDY 28.2 Beware of space invaders in the library (Felipe & Sommer, 1966)

- The unsuspecting participants were female university students studying at a large table (1m x 5m) with six chairs evenly spaced on either side of the table. There were at least two empty chairs on either side of each student, and one opposite.
- There were five experimental conditions in which the female experimenter:
  - a sat next to the student and moved her chair to within about 8 cm of the student's (about as close as possible without actually touching); if the student moved her chair away, the experimenter would move her chair nearer
  - b sat in the chair next to the student at a normal, acceptable distance (about half a metre)
  - c sat two seats away from her (leaving one chair between them)
  - d sat three seats away
  - e sat immediately opposite her (about a metre apart).
- About 55 per cent of the participants in condition (a) stayed in the library for longer than 10 minutes, compared with 90 per cent in conditions (b)–(e) combined; 100 per cent of participants in a control condition (who sat at the same-sized table, with the same number and arrangement of empty chairs, but weren't 'invaded' by the experimenter) stayed longer than 10 minutes.
- After 20 minutes, these percentages reduced to 45 per cent in the first condition, 80 per cent in (b)–(e). and just below 100 per cent in the control condition.
- By the end of the 30-minute experiment, the figures were 30 per cent, 73 per cent and 87 per cent respectively.
- Students were more likely to leave, move away, adjust their chair or erect barriers (such as putting a bag on the table between themselves and the 'intruder') in condition (a).

Similar results were found for male psychiatric patients (Felipe & Sommer, 1966), and for people sitting on park benches (Sommer, 1969). In Hall's (1959, 1966) terms, the stranger in Felipe and Sommer's studies was invading the student's *personal space.* This describes the human behaviour resembling the 'individual distance' of zoo animals (the distance that two individuals of the same species try to keep between each other: Hediger, 1951).

Box 28.7 Personal space

Personal space is a sort of invisible bubble that surrounds us. According to Hall, we learn *proxemic rules* that prescribe:

- the amount of physical distance that's appropriate in daily relationships, and
- the kinds of situations in which closeness or distance are proper.

Hall identifies four main regions or zones of personal space. (See Figure 28.3 on next page.)

There are important *cultural differences* regarding proxemic rules. Each zone of personal space allows the use of different cues of touch, smell, hearing and seeing, which are more important in some cultures than others. Watson & Graves (1966) observed discussion groups of Americans and those from Arab countries; in the latter, there was more direct face-to-face orientation, greater closeness and touching.

South Americans and Arabs have been called *'contact cultures'*, while the Scots and Swedes have been called *'non-contact cultures'*.

The *caste system* in India represents a highly formalised, institutionalised set of proxemic rules.

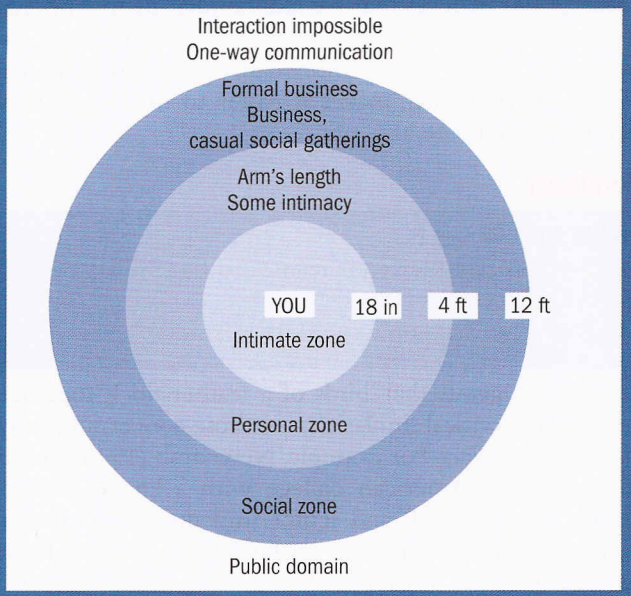

Figure 28.3 Hall's four zones of personal space (from Nicholson, 1977)

A similar concept to personal space is the *body-buffer zone*, the point at which a person begins to feel uncomfortable when approached by another. Criminals convicted of violent crimes compared with non-criminals, and schizophrenics compared with other kinds of psychiatric patients, tend to have *larger* body-buffer zones, that is, they more easily begin to feel uneasy when others walk towards them (Nicholson, 1977).

Our feelings for others may depend on whether proxemic rules are followed, and these rules are themselves influenced by the nature of the relationship. For instance, relatives and intimate friends are allowed much closer proximity – and bodily contact – than mere acquaintances or strangers. As far as bodily contact is concerned, there are different rules for different relatives depending on their gender, and this applies to friends too (see Figure 28.4).

Proximity is just one of several kinds of *social act* which make up the degree of intimacy that exists between two people. According to Argyle & Dean (1965), we all have a dual tendency to approach others and seek their company, and to avoid them and remain separate and independent. The balance between these two opposing tendencies is 'negotiated', non-verbally, in each social situation, so that we try to find a level of intimacy we feel comfortable with.

Successful friendships may require an initial establishment of *boundary understandings*. In Hall's terms, strangers must be 'invited' into our intimate zone and not 'trespass' from an initial casual personal distance. In terms of Argyle

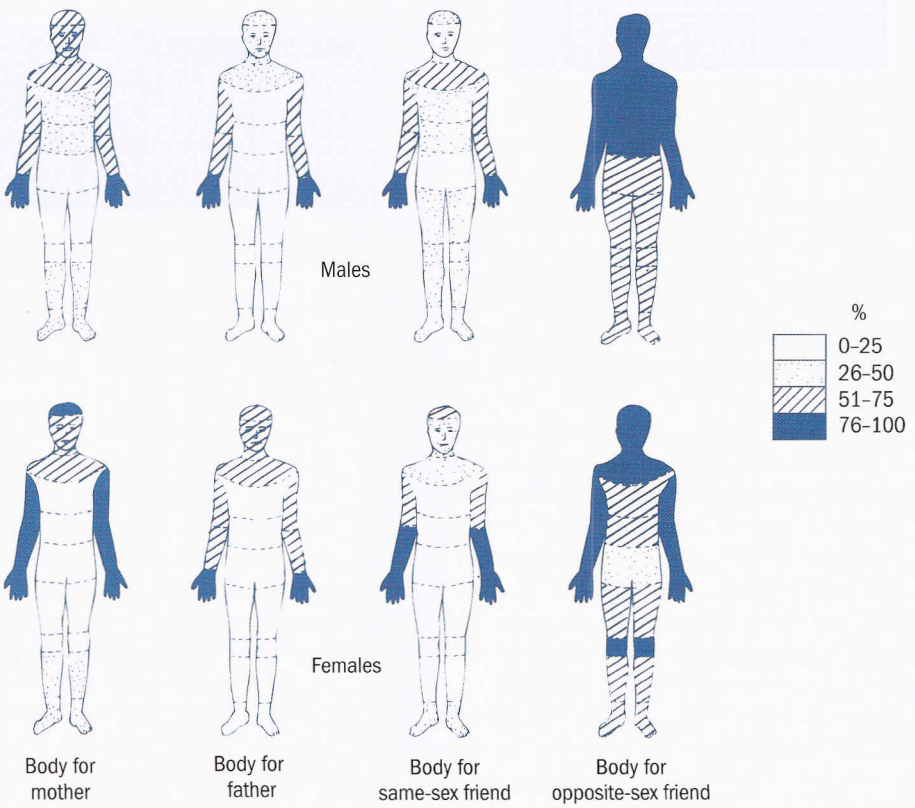

Figure 28.4 Male and female 'bodies for others', as experienced through the amount of touching received from others (Jourard, 1966)

and Dean's equilibrium model of intimacy, strangers (like the experimenter in Sommer's studies) who make a situation uncomfortably intimate too soon are unlikely to become friends.

ASK YOURSELF...

- Do you think it's ethically acceptable to conduct research like Sommer and Felipe's 'library study'?

Exposure and familiarity

Proximity increases the opportunity for interaction (*exposure*), which, in turn, increases *familiarity*. There's considerable evidence that, far from breeding contempt, familiarity breeds fondness (the *mere exposure effect*: Zajonc, 1968). For example, the more times university students saw photographs of men's faces, the more they liked them (Zajonc, 1968).

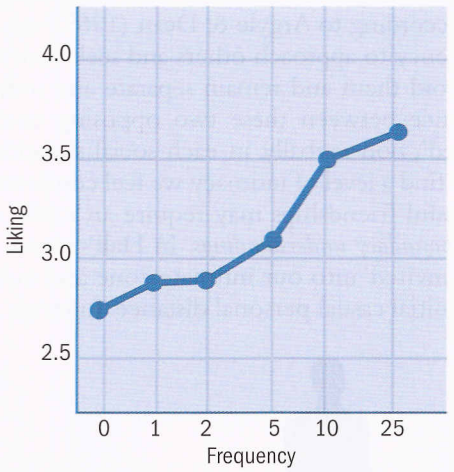

Figure 28.5 The relationship between frequency of exposure and liking. Participants were shown photographs of different faces and the number of times each face was shown was varied. The more they saw a particular face, the more they said they liked the person shown (based on Zajonc, 1968)

According to Argyle (1983), the more two people interact, the more *polarised* their attitudes towards each other become, usually in the direction of greater liking. This, in turn, increases the likelihood of further interaction, but only if the interaction is on an equal footing.

People form friendships with those they encounter frequently (as the mere exposure effect would predict). Asian-Americans date Euro-Americans when they're in close proximity (Fujino, 1997), high-school students form friendships within their own academic subjects (Kubitschek & Hallinan, 1998), and older, relocated adults make friends among their nearest neighbours (Dugan & Kivett, 1998).

This preference for what is familiar extends to our own facial appearance. Mita *et al.* (1977) photographed women students and later showed each student her actual picture together with a mirror-image of it. Most students preferred the latter – this is how we're used to seeing ourselves – while their friends preferred the former – this is how others are used to seeing us!

ASK YOURSELF...

- What is it about familiarity that makes it an influence on attraction?
- Why should we prefer the familiar?

Fiske (2004) believes that we like familiar people because we feel we can understand them easily. If we (think we) understand them, we can more easily predict their behaviour, which, in turn, makes it easier to influence them. Familiar people are also safe.

Similarity

ASK YOURSELF...

- Do you consider your friends to be similar to you? If so, in what ways?
- Does this also apply to sexual partners?

Evidence suggests that 'birds of a feather flock together', and that the critical similarities are those concerning *beliefs*, *attitudes* and *values*. For example, Newcomb (1943) studied students at an American college with a liberal tradition among teaching staff and senior students. Many students coming from conservative backgrounds adopted liberal attitudes in order to gain the liking and acceptance of their classmates. Griffitt & Veitch (1974) paid 13 males to spend ten days in a fall-out shelter. Those with similar attitudes and opinions liked each other most by the end of the study, particularly if they agreed on highly salient issues.

ASK YOURSELF...

- What is it about similarity that makes it an influence on attraction?
- Why should we prefer people who (we believe) are like us?

Rubin (1973) suggests that similarity is rewarding because:

- agreement may provide a basis for engaging in joint activities
- a person who agrees with us helps to increase our confidence in our own opinions, which enhances our self-esteem; according to Duck (1992), the validation that friends give us is experienced as evidence of the accuracy of our *personal constructs* (see Chapter 42)
- most people are vain enough to believe that anyone who shares their views must be a sensitive and praiseworthy individual
- people who agree about things that matter to them generally find it easier to communicate
- we may assume that people with similar attitudes to ourselves will like us, and so we like them in turn (*reciprocal liking*).

According to Fiske (2004), if someone resembles prior experience or the self, then at least we have the illusion of knowing 'what makes them tick'. In this respect, familiarity

and similarity influence attraction in comparable ways. We mostly seek out others who make us feel good about ourselves:

> ... People who resemble us or agree with us also reassure us. People who validate us and like us presumably won't do us any harm ... (Fiske, 2004)

According to the *similarity-attraction principle,* if familiarity underlies attraction, and if the most familiar people are those who are like us, then people like us are attractive. This stems in part from *consistency theories of attitude change* (see Chapter 24). The most relevant here is Heider's (1958) *balance theory.* People prefer and infer affective, cognitive and behavioural consistency – in themselves and others. Psychologically related individuals will see each other as similar if they like each other, and they'll see each other as likeable if they're similar. In other words, people like to agree with their friends and to befriend those who agree with them. This describes *interpersonal balance,* 'a harmonious state, one in which the entities comprising the situation and the feelings about them fit together without stress' (Heider, 1958).

Physical attractiveness

While it often takes time to find out about other people's attitudes and values, their physical attractiveness is immediately apparent. Physical attractiveness has been studied as an influence on attraction in its own right, as well as one aspect of similarity.

The attractiveness stereotype

As we saw in Chapter 22, we tend to perceive attractive-looking people as also having more attractive personalities (the *attractiveness stereotype*). Dion *et al.* (1972) found that photographs of attractive people, compared with unattractive people, were consistently credited with more desirable qualities – sexually warm and responsive, kind, strong, outgoing, nurturant, sensitive, interesting, poised, sociable, exciting dates, better character, happily married, socially and professionally successful and enjoying more fulfilling lives. So, 'what is beautiful is socially good' (Fiske, 2004).

The power of the physical attractiveness stereotype is demonstrated in a classic study by Snyder *et al.* (1977).

KEY STUDY 28.3 The self-fulfilling nature of the attractiveness stereotype (Snyder *et al.*, 1977)

- Male undergraduates received photographs of women before a getting-acquainted telephone conversation.
- The photographs, independently rated as either quite attractive or quite unattractive, didn't depict their actual partners, who were unaware of the experimental manipulation.
- Before the telephone conversation, the men rated the supposedly attractive partner as more sociable, poised, humorous and adept.
- During the conversation, independent judges rated these men as more sociable, sexually warm, outgoing, interesting, independent, bold, humorous and adept.
- In response, their (actual) partners, who'd been randomly allocated to the 'attractive' or 'unattractive' conditions, behaved in similar ways.
- The men's expectations about their partners, based on the photographs, created a *self-fulfilling prophecy.*

However, Dermer & Thiel (1975) found that extremely attractive women were judged (by female participants) to be egotistic, vain, materialistic, snobbish and less likely to be successfully married. This suggests that it's not always to our advantage to be seen as highly attractive, and one situation where this may apply is where a criminal's good looks played a part in the crime.

Dion & Dion (1995) observe that stereotyping based on facial attractiveness appears at least as early as six years old. They also suggest that this might be linked to the *just world hypothesis,* such that there's a positive bias towards 'winners', equivalent to 'blaming the victim' (see Chapter 23).

Is the attractiveness stereotype culturally relative?

Like most attractiveness research, studies of the attractiveness stereotype are American, the prime example of an individualist culture. Although a physical attractiveness stereotype can be found in some collectivist cultures (such as Korea and Taiwan), the content differs. For example, in Korea attractive people aren't seen as more powerful but as showing more concern for others and more integrity. In other words, 'the beautiful receive the benefits of social status, embodying that culture's ideal values' (Fiske, 2004).

What makes someone attractive?

Different cultures have different criteria concerning physical beauty. For example, chipped teeth, body scars, artificially elongated heads and bound feet have all been regarded as beautiful, and in western culture, definitions of beauty change over time, as in the 'ideal' figure for women (see Chapter 44.) Traditionally, men have emphasised physical attractiveness, including facial beauty, more than women have. But women haven't been disinterested in men's appearance: their stature, particularly height, plus a muscular body and (currently) firm, rounded buttocks influence how attractive they're judged to be (by women, anyway!). Nor are they indifferent about men's facial appearance.

According to Brehm (1992), in the context of personal ads and commercial dating services, the primary 'resource' (or reward) offered by females seeking a male partner is still physical attractiveness, which matches what men are actually seeking from a female partner. But this appears to be an almost universal male preference, not one confined to western culture (Buss, 1989: see below, page 487).

Jude Law in *The Talented Mr Ripley* (1999)

> ***ASK YOURSELF...***
> - Think of someone you find extremely facially attractive, and try to specify what it is about their face that you like.

Defining facial attractiveness

The idea that beauty is in the eye of the beholder stems from the philosopher, Hume (1757). This implies, of course, that beauty cannot be defined objectively,. However, although any two individuals can vary widely in what they consider facially attractive, these differences actually vary around an underlying norm, which is surprisingly consistent across cultures (Berry, 2000; Langlois & Roggman, 1990). Langlois *et al.* (1987) found that when babies under one year are shown faces that adults consider attractive or unattractive, they spend longer looking at the former (implying that they prefer them: see Chapter 16). Clearly, they're too young to have learned cultural standards of beauty.

Langlois & Rogmann (1990) took photographs of faces with standard pose, expression and lighting, and then scanned them into a computer. Each image was then divided into a very large number of tiny squares (or *pixels*), and the brightnesses of corresponding pixels in different same-sex faces were *averaged* to produce *computer-composite images.* When people were asked to judge the attractiveness of these composite faces (made from four, eight, 16, or 32 faces), they rated them as increasingly attractive the more faces that went into each image. This applied to both male and female faces.

The greater the number of faces making up a composite image, the more the peculiarities of particular faces become ironed out. Hence, as Bruce & Young (1998) observe:

> It seems that moving a facial image closer to the average ... increases its perceived attractiveness ...

Computer-composite faces. The columns show composite sets created from female faces (left) or from male faces (right). From top to bottom, rows show composites created by averaging across 4, 8, 16 and 32 faces (from Bruce & Young, 1998)

If this is a genuine phenomenon, how can we explain it? Bruce and Young suggest two possible explanations:

- although we've not seen composite faces before, *averaged* faces (close to the average of faces we *have* see before) are preferred because they seem *familiar* (seen above, page 480). This is consistent with the idea that attractive people are seen as possessing high status – that is, they represent the 'culturally good and the socially desirable' (Fiske, 2004)
- individuals whose characteristics are close to the average of the population might be preferred, because they're less likely to carry harmful genetic mutations (Langlois & Roggman, 1990).

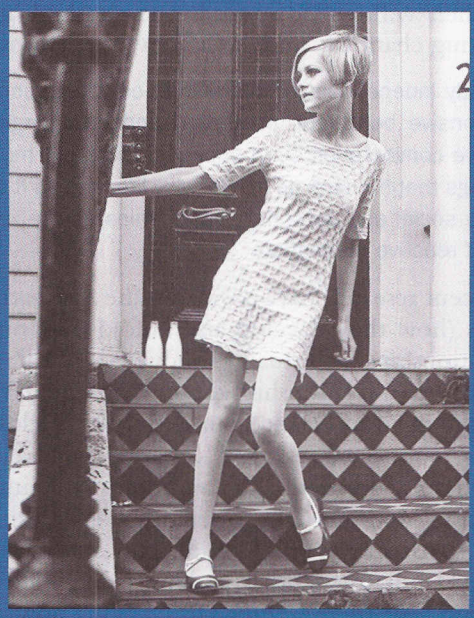
A third possible explanation (an almost 'obvious' one) is that average features (by definition) omit every 'too': too big, too small, too short, too long, and so on (Fiske, 2004).

Is attractiveness really no more than averageness? This seems unlikely. For example, if we describe someone as 'average looking', we usually mean that s/he is neither 'good-looking' nor 'ugly', and movie stars and sex symbols *aren't* obviously average (otherwise most of us would be sex symbols!).

According to Perret *et al.* (1994), the average derived from highly attractive faces is consistently preferred to the average of the entire set of photographs they were taken from. This wouldn't happen if 'attractive' equalled 'average. When the difference between the average shape of attractive faces and the average shape of the entire set was increased, perceived attractiveness of the former also increased. But the effect of this was to make the resulting faces *more different* from the average. Perret *et al.* found exactly the same pattern of results for European and Japanese faces, regardless of whether they were judged by European or Japanese people.

We also seem to prefer more *symmetrical* faces. While most faces (to varying degrees) are, in fact, asymmetrical around the vertical midline, even those with only slight asymmetry can be made more attractive (Bruce & Young, 1998).

In addition, having younger-looking features, for both sexes, seems to be an advantage. For women, 'favourites' include child-like features (large eyes, spaced far apart, small chin and nose), narrow face and prominent cheek-bones, expressive features (high eyebrows and large smile), and sexual cues (larger lower lip and well-groomed, full hair). The recent trend in cosmetic surgery for full lips has resulted, for some, in a bizarre change of appearance.



Actress Lesley Ash – the after photo

Facial attractiveness in men is less often studied, but high cheekbones and a rugged jaw seem to be favoured (Berry, 2000).

From a *sociobiological* perspective (see Chapter 2), attractive facial features may signal sexual maturity or fertility. This is also consistent with the tendency to equate beauty with youthfulness (but see Chapters 22 and 39, and Box 28.8).

Box 28.8 The sociobiology of beauty

- According to Singh (in Charter, 1995), anyone whose waist size exceeds their hip measurement (i.e. whose *waist-hip ratio* – WHR – is greater than one) is much more at risk from heart disease and diabetes.
- Furthermore, Singh claims to have shown that women with a waist-hip ratio of 0.7 have universal appeal as potential partners, because their body shape transmits signals about health, sexual maturity, and fertility. For males the ideal is more like 0.85–0.9.
- This fits in perfectly with Darwinian theories of human mate selection, which claim that both men and women select partners who enable them to enhance reproductive success, thus ensuring the survival of their genes into the next generation (see Chapter 2 and Gross & Rolls, 2004).
- Twiggy's WHR was a surprising 0.73 (her vital statistics were 31–24–33), and although *Playboy* centrefolds have shown a 20 per cent decline in plumpness over the years (see Chapter 44), they've shown a consistent WHR of 0.7.
- Singh has been criticised on several grounds. The diseases he claims are correlated with high WHRs affect mainly older (post-menopausal) women, and so aren't relevant to mating. They're also historically quite recent.

As well as her facial beauty, 1960s model Twiggy's waist-hip ratio was (surprisingly) an attractive 0.73

The matching hypothesis

According to *social exchange theory* (e.g. Thibaut & Kelley, 1959: see below), people are more likely to become romantically involved if they're fairly closely matched in their ability to reward one another. Ideally, we'd all have the 'perfect partner' because, the theory says, we're all selfish. But since this is impossible, we try to find a compromise solution. The best general bargain that can be struck is a *value-match,* a subjective belief that our partner is the most rewarding we could realistically hope to find.

Several studies have tested the *matching hypothesis* (Walster *et al.*, 1966; Dion & Berscheid, 1974; Berscheid *et al.*, 1971; Silverman, 1971; Murstein, 1972; Berscheid & Walster, 1974). These studies generally show that people rated as being of high, low or average attractiveness tend to choose partners of a corresponding level of attractiveness. Indeed, according to Price & Vandenberg (1979):

> The matching phenomenon [of physical attraction between marriage partners] is stable within and across generations.

The findings from the various matching hypothesis studies imply that the kind of partner we'd be satisfied with is one we feel won't reject us, rather than one we positively desire. Brown (1986), however, maintains that the matching phenomenon results from a well-learned sense of what's 'fitting', rather than a fear of being rebuffed. For Brown, we learn to adjust our expectations of rewards in line with what we believe we have to offer others.

An evaluation of attraction research

According to Duck (1999), the 'magnetic metaphor' of attraction implies that people are unwittingly, and almost against their will, pulled towards one another's inherent, pre-existing characteristics. It's a view of relationships as:

> ... implicitly independent of interaction, co-construction, mutually responsive behaviour, or shared understandings derived from active conversation ... In short, it leaves out most of the other things that humans do in everyday life, and so it serves to caricature social and personal relationships as the unthinking domain of reactive magnetism ...

More recent research has considered the *dynamics* of relationships (how they develop and unfold over time), and how relationships are actually conducted in real life. One feature of 'real' relationships is their inherent tensions, such as the need to balance our desire for disclosure and openness, connectedness and interdependence on the one hand, and the desire for autonomy and independence, privacy and the right to retain secrets on the other.

Not surprisingly, this shift has involved fewer controlled laboratory studies, and more exploration of life as it's lived 'out there' (Duck, 1999). This now includes such diverse research areas as *homosexual* and *electronic* (online or cyberspace) relationships (see above).

WHAT KEEPS PEOPLE TOGETHER?

ASK YOURSELF...

- What do all the important relationships in your life have in common?

You may say something to the effect that they provide you with security, happiness, contentment, fun and so on, and (if you're honest) that they can also be complex, demanding and, at times, even painful. If all relationships involve both positive and negative, desirable and undesirable aspects, what determines our continued involvement in them?

Social exchange theory

Social exchange theory (SET) provides a general framework for analysing all kinds of relationship, both intimate and non-intimate, and is really an extension of *reward theory* (see above, page 478).

According to Homans (1974), we view our feelings for others in terms of profits (the amount of reward obtained from a relationship minus the cost). The greater the reward and lower the cost, the greater the profit and hence the attraction. Blau (1964) argues that interactions are 'expensive': they take time, energy and commitment, and may involve unpleasant emotions and experiences. Because of this, what we get out of a relationship must be more than what we put in.

Similarly, Berscheid & Walster (1978) argue that in any social interaction there's an exchange of rewards (such as affection, information and status), and that the degree of attraction or liking will reflect how people evaluate the rewards they receive relative to those they give.

ASK YOURSELF...

- Is it appropriate to think of relationships in this economic, capitalistic, way?
- Are relationships really like that?

An evaluation of SET

Social exchange theory sees people as fundamentally selfish and human relationships as based primarily on self-interest. But this is a *metaphor* for human relationships, and it shouldn't be taken too literally. However, although we like to believe that the joy of giving is as important as the desire to receive, we have to admit that our attitudes toward other people are determined to a large extent by our assessments of the rewards they hold for us (Rubin, 1973).

Equally, though, Rubin believes that SET doesn't provide an adequate, complete account:

> Human beings are sometimes altruistic in the fullest sense of the word. They make sacrifices for the sake of others without any consideration of the rewards they will obtain from them in return ...

Altruism is most often and most clearly seen in close interpersonal relationships (see Chapter 30).

Indeed, some psychologists make the distinction between 'true' love and friendship, which are altruistic, and less admirable forms which are based on considerations of exchange (Brown, 1986). Fromm (1962) defines true love as giving, as opposed to the false love of the 'marketing character' which depends upon expecting to have the favours returned. Support for this distinction comes from studies by Clark & Mills (1979, 1993),who identified two kinds of intimate relationship:

- the *communal couple,* in which each partner gives out of concern for the other
- the *exchange couple,* in which each keeps mental records of who's 'ahead' and who's 'behind'.

SET implies that *all* relationships are of the exchange variety. Exchange might describe some kinds of relationship, such as impersonal friendships and relationships between business associates, but in communal relationships, people don't track outcomes (who did what for whom: Clark, 1984). Instead, they track each other's needs, and one partner may need more than the other, at different times, or even throughout the relationship (Clark *et al.*, 1986). Fiske (2004) suggests that thinking of family relationships as communal explains why parents don't normally 'charge' their children for their upbringing. According to Clark & Grote (1998), communal relationships operate by different norms from exchange relationships.

One of those norms is *reciprocity,* which involves the repayment of specific benefits ('you scratch my back, and I'll scratch yours': see Chapter 27). Perhaps contrary to what most people would expect, reciprocity is particularly strong in most casual relationships, but weaker in more intimate communal relationships (Clark & Mills, 1993). Indeed, 'exchange' implies that people reciprocate benefit for benefit, resulting in an *equivalence* of outcomes (Fiske, 2004). The communal couple's responsiveness to each other's needs represents a broader type of reciprocity. In some form, reciprocity appears to be a fundamental aspect of human social exchanges (Dovidio & Penner, 2004), evident in all known cultures (Moghaddam *et al.*, 1993).

Clearly, SET is a greatly oversimplified account of human relationships. It simply cannot accommodate the rich diversity and complexity of relationships. At best, it may describe a certain type of superficial and probably short-term relationship.

Equity theory

SET is really a special case of a more general account of human relationships called *equity theory* (ET). The extra component in ET that's added to reward, cost and profit is *investment*. For Brown (1986):

> A person's investments are not just financial; they are anything at all that is believed to entitle him to his rewards, costs, and profits. An investment is any factor to be weighed in determining fair profits or losses.

Equity *doesn't* mean equality (as implied by 'exchange'), but a *constant ratio* of rewards to costs or profit to investment. So, equity theory involves a concern with *fairness,* and it's *changes* in the ratio of what you put in and what you get out of a relationship which are likely to cause changes in how you feel about it, rather than the initial ratio. You may believe it's fair and just that you give more than you get, but if you start giving very much more than you did and receiving proportionately less, then you're likely to become dissatisfied.

An evaluation of ET

ET is an improvement on SET, and it seemed to predict satisfaction and liking in relationships (Walster *et al.*, 1978). But relationships *don't* become more equitable over time, and equity *doesn't* predict the stability or quality of relationships over time (Van Yperen & Buunk, 1990).

However, some versions of SET do actually take account of factors other than the simple and crude profit motives of social interactors. One of these was introduced by Thibaut & Kelley (1959).

Box 28.9 The concepts of comparison level and comparison level for alternatives (Thibaut & Kelley, 1959)

- *Comparison level* (CL) is essentially the average level of rewards and costs you're used to in relationships, and is the basic level you expect in any future relationship. So, if your current reward:cost ratio falls below your CL, the relationship will be unsatisfying. If it's above your CL, you'll be satisfied with the relationship.
- *Comparison level for alternatives* (CL alt.) is essentially your expectation about the reward:cost ratio which *could* be obtained in other relationships. If your current ratio in a relationship exceeds the CL alt., then you're doing better in it than you could do elsewhere. As a result, the relationship should be satisfying and likely to continue. But if the CL alt. exceeds your current reward:cost ratio, then you're doing worse than you could do elsewhere. As a result, the relationship should be unsatisfying and unlikely to continue.

According to Duck (1988), the concept of CL alt. implies that the endurance of a relationship (as far as one partner is concerned) could be due to:

- the qualities of the other partner and the relationship
- the negative and unattractive features of the perceived alternatives, or
- the perceived costs of leaving.

But this still portrays people as being fundamentally selfish, and many researchers (e.g. Duck, 1988; Walster *et al.*, 1978) prefer to see relationships as being maintained by an equitable distribution of rewards and costs for both partners. In this approach, people are seen as being concerned with the equity of outcomes for both themselves and their partners.

Murstein *et al.* (1977) argue that concern with either exchange or equity is negatively correlated with marital adjustment. People in close relationships don't think in terms of rewards and costs at all – until they start to feel dissatisfied (Argyle, 1987). Murstein & MacDonald (1983) have argued that although the principles of exchange and equity play a significant role in intimate relationships, a conscious concern with 'getting a fair deal', especially in the short term, makes *compatibility* (see below) very hard to achieve. This is true in both friendship and, especially, marriage. This corresponds to Clark and Mills's *exchange couple* (see above).

Complementarity

ASK YOURSELF...

- Think of your most successful relationship(s) – past and/or present.
- What made it/them work?
- Did the 'essential ingredients' change as the relationship(s) developed?

According to Kerckhoff & Davis's (1962) filter model (see above), *complementarity of needs* becomes increasingly important as relationships become long-term. According to Winch (1958), happy marriages are often based on each partner's ability to fulfil the needs of the other. For example, a domineering person could more easily satisfy a partner who needs to be dominated than one who's equally domineering, and Winch found some empirical support for this view.

Although some complementarity may evolve as a relationship develops, people seem, if anything, slightly more likely to marry those whose needs and personalities are *similar* (the *matching phenomenon*) (e.g. Berscheid & Walster, 1978). Indeed, Berscheid & Reis (1998) argue that the overwhelming evidence favours similarity:

> ... Altogether, support is weak for people's intuition that opposites, exotics, or mysteries form the primary basis for attraction, whereas support is strong for the similarity-attraction principle.

In direct contradiction of the opposites-attract hypothesis, Felmlee (1998) examined 'fatal attractions' to a partner with qualities that differed from the partner and from the average. Descriptions of these terminated relationships indicated that even when these dissimilar, unique or extreme qualities might have been intriguing or appealing to begin with, it was the self-same qualities that eventually produced disenchantment.

Complementarity of resources

Instead of complementary needs, what about complementarity in resources (Brehm, 1992)? As we noted earlier, men seem to give a universally higher priority to 'good looks' in their female partners than do women in their male partners, while the situation is reversed when it comes to 'good financial prospect' and 'good earning capacity'. Based on a study of 37 cultures (including Nigeria, South Africa, Japan, Estonia, Zambia, Columbia, Poland, Germany, Spain, France, China, Palestinian Arabs, Italy and The Netherlands) involving over 10,000 people, Buss (1989) concluded that these sex differences 'appear to be deeply rooted in the evolutionary history of our species'.

CRITICAL DISCUSSION 28.1 Do our genes dictate what we want in a mate?

- According to Buss (1988, 1989), the chances of reproductive success should be increased for men who mate with younger, healthy adult females, as opposed to older, unhealthy ones. Fertility is a function of the mother's age and health, which also affects pregnancy and her ability to care for her child.
- Men often have to rely on a woman's physical appearance in order to estimate her age and health, with younger, healthier women being perceived as more attractive (see Box 28.8).
- Women's mate selection depends on their need for a provider to take care of them during pregnancy and nursing: men seen as powerful and controlling resources that contribute to the mother and child's welfare will be seen as especially attractive.
- Buss's sociobiological explanation removes male–female relationships from their cultural or historical context. This

is captured in the use of the term 'mate selection', which is normally used to describe non-human animals.
- Perhaps women have been forced to obtain desirable resources through men, because they've been denied direct access to political and economic power. Traditionally, a woman has been regarded as the man's property, whereby her beauty increases his status and respect in others' eyes.
- Buss conveniently seems to overlook a major finding from his (1989) study: 'kind' and 'intelligent' were universally ranked as *more important* than 'physically attractive' or 'good earning power' by both men and women!
- Simpson *et al.*'s (1986) findings that women are increasingly marrying for reasons ***other than*** material necessity contradict Buss's sociobiological explanation (see above, page 475).
- How can Buss's argument account for homosexual relationships, which clearly don't contribute to the survival of the species, but which are subject to many of the same sociopsychological influences involved in heterosexual relationships (Brehm, 1992)?

Compatibility

The importance of similarity

Complementarity, as far as it exists, can be seen as a component of *compatibility,* but *similarity* plays a much larger part in keeping couples together. For example, individuals with similar needs (Meyer & Pepper, 1977), attitudes, likes and dislikes (Newcomb, 1978), and who are similar in attractiveness (White, 1980), are more likely to remain in a relationship than dissimilar individuals.

KEY STUDY 28.4 Do birds of a feather stay together?
- Hill *et al.* (1976) studied 231 steadily dating couples over a two-year period, at the end of which 103 couples (45 per cent) had broken up.
- The surviving couples tended to be more alike in terms of age, intelligence, educational and career plans, as well as physical attractiveness. Those who split up often mentioned differences in interests, background, sexual attitudes and ideas about marriage.
- About 80 per cent of the couples who described themselves as being 'in love' at the start stayed together, compared with 56 per cent who didn't. Of couples in which both members initially reported being equally involved in the relationship, only 23 per cent broke up, but where one member was much more involved than the other, 54 per cent did so.
- The latter is a highly unstable couple, in which the one who's more involved (putting more in but getting less in return) may feel dependent and exploited, while the one who's less involved (putting less in but getting more in return) may feel restless and guilty (which implies some sense of fairness).

Jack and Vera Duckworth from *Coronation Street* – complementarity personified!

Marital satisfaction

This is another way of looking at compatibility. In a review of studies looking at marital satisfaction and communication, Duck (1992) found that happy couples give more positive and consistent non-verbal cues than unhappy couples, express more agreement and approval for the other's ideas and suggestions, talk more about their relationship, and are more willing to compromise on difficult decisions.

Lauer & Lauer (1985) asked several hundred couples married for at least 15 years why they thought their marriage had lasted. They stressed *friendship* (e.g. 'My spouse is my best friend'), *commitment* ('Marriage is a long-term commitment'), *similarity* ('We agree on how and how often to show affection'), and *positive affect* ('We laugh together') as the basic elements in an enduring relationship. These findings could be seen as implying a successful transition from passionate to companionate love.

RELATIONSHIP BREAKDOWN AND DISSOLUTION

ASK YOURSELF...
- Think of your most unsuccessful relationship(s).
- Why did it/they go wrong?
- Was it to do with you as individuals, or 'circumstances', or a mixture of the two?

Why do relationships go wrong?

According to Duck (2001), there's an almost infinite number of reasons why relationships break up. But they can be put into three broad categories:

1. *pre-existing doom:* incompatibility and failure are almost predestined (for example, 'Schoolgirl, 17, marries her 50-year-old teacher, who's already a grandfather')

2. *mechanical failure:* two suitable people of goodwill and good nature nevertheless find they cannot live together (this is the most common cause)
3. *sudden death:* the discovery of a betrayal or infidelity can lead to the immediate termination of a romantic relationship (see below).

Duck believes that the 'official' reasons given to others (including the partner) to justify the break-up are far more interesting psychologically than the real reasons. The psychology of break-up involves a whole layer of individual psychological processes, group processes, cultural rules and self-presentation. But this applies mainly to romantic relationships, rather than friendships.

When you fall out with a friend, there's usually no formal or public 'announcement'. There's no need for this, because friendships aren't exclusive in the way that most sexual relationships are (it's 'normal' to have several friends at once, but not several partners!). As Duck says:

> ... Truly committed romantic relationships necessarily involve the foregoing of other romantic relationships and commitment to only one partner ('forsaking all others', as it says in the marriage ceremony) ...

Marital unhappiness and divorce

Duck (1988, 1992) has identified several factors that make it more likely that a marriage will be unhappy and/or end in divorce.

- Marriages in which the partners are *younger than average* tend to be more unstable. This can be understood by reference to Erikson's concept of *intimacy* (see Chapter 38). Such marriages often involve early parenthood; the young couple has little time to adjust to the new responsibilities of marriage before financial and housing problems are added with the arrival of a baby (Kellmer Pringle, 1986).
- Marriages between couples from *lower socio-economic groups* and *educational levels* tend to be more unstable. These are also the couples which tend to have their children very early in marriage.
- Marriages between partners from *different demographic backgrounds* (race, religion, and so on.) also tend to be more unstable. This can be related to Kerckhoff and Davis's filter model.
- Marriages between people who've experienced *parental divorce* as children, or who've had a greater *number of sexual partners* than average before marriage tend to be more unstable.

While these factors are important, only a proportion of marriages involving young, lower class individuals or those from different cultural backgrounds and so on actually end in divorce. Conversely, many divorces will involve couples who don't fit any of these descriptions. So what other factors may be involved?

According to Brehm (1992), there are two broad types of cause: *structural* (gender, duration of the relationship, the presence of children and role strain created by competing demands of work and family) and *conflict resolution*.

Gender differences

Men and women seem to differ in their perception of problems in a relationship. In general, women report more problems, and there's some evidence that the degree of female dissatisfaction is a better predictor than male unhappiness of whether the relationship will end. This could be because women are more sensitive to relationship problems than men. Alternatively, men and women may come into relationships with different expectations and hopes, with men's generally being fulfilled to a greater extent than women's.

Consistent with this possibility is evidence of gender differences in the specific type of problems that are reported. For example, divorcing men and women are equally likely to cite communication problems as a cause of their splitting up. But women stress basic unhappiness and incompatibility more than men do.

Men also seem particularly upset by 'sexual withholding' by a female partner, while women are distressed by a male partner's sexual aggression. This is consistent with the finding that men tend to fall in love more easily than women (Baumeister & Bratslavsky, 1999), which is contrary to the popular myth about women demanding commitment and men fighting shy of it. Men also seem to respond more quickly to any intimacy changes (positive and negative), at both earlier and later stages of a relationship (Fiske, 2004).

Duration of relationships and the passage of time

The longer partners have known each other before marriage, the more likely they are to be satisfied in the marriage, and the less likely they are to divorce. However,

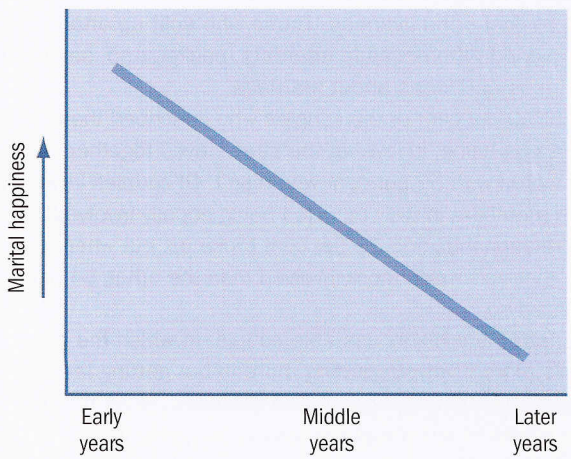


Figure 28.6 A linear life-cycle (based on Brehm, 1992)

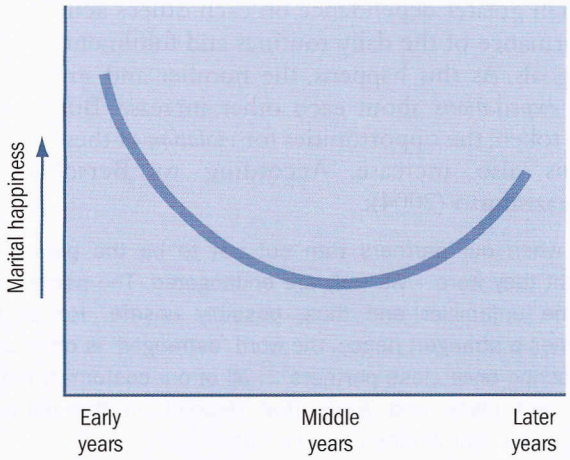

Figure 28.7 A curvilinear life cycle (based on Brehm, 1992)

couples who've have cohabited before marriage report fewer barriers to ending the marriage, and the longer a relationship lasts, the more people blame their partners for negative events.

Two major views of changes in marital satisfaction over time are Pineo's (1961) *linear model* and Burr's (1970) *curvilinear model*. According to the linear model, there's an inevitable fading of the romantic 'high' of courtship before marriage. Also, people marry because they've achieved a 'good fit' with their partner. So, any changes that occur in either partner will reduce their compatibility. For example, if one partner becomes more self-confident (ironically, through the support gained from the relationship), there may be increased conflict between two 'equals' competing for superiority.

The curvilinear model (see Figure 28.7) proposes that marital happiness is greatest in the earliest years. Marital satisfaction declines as children are born and grow up, then increases again as they mature and leave home.

While it's generally agreed that there's a decline in satisfaction during the early years, whether there's an actual increase or just a levelling off after that remains a matter of debate. Gilford & Bengtson (1979) argue that it's an oversimplification to talk about 'marital satisfaction'. Instead, we should look at two life cycles: the *pattern of positive rewards,* and the *pattern of negative costs.* The early years are associated with very high rewards and very high costs, while in the middle years there's a decline in both. In the later years, costs continue to decline, but there's an increase in rewards.

Conflict resolution

According to Duck (1988), some kind and degree of conflict is inevitable in all relationships. But the process of resolving conflicts can often be positive, promoting growth of the relationship (Wood & Duck, 1995).The important question, therefore, isn't whether there's conflict, but *how* it's handled. However, recurring conflicts may indicate an inability to resolve the underlying source; the partners may come to doubt each other as reasonable persons, leading to a 'digging in of the heels', a disaffection with each other and, ultimately, a 'strong falling out' (Berry & Willingham, 1997).

Some degree of overt conflict ('getting it out in the open') can improve a relationship – talking it through and working it out. But differences can result in destructive behaviour, in which partners fail to accommodate to each other's needs. This, in turn, can produce a *conflict spiral,* where one partner responds to the other's negative emotion with negative emotion, and so on. *Unregulated couples,* who don't balance their negative reactions with at least an equal number of positive ones, are headed for trouble (Fiske, 2004).

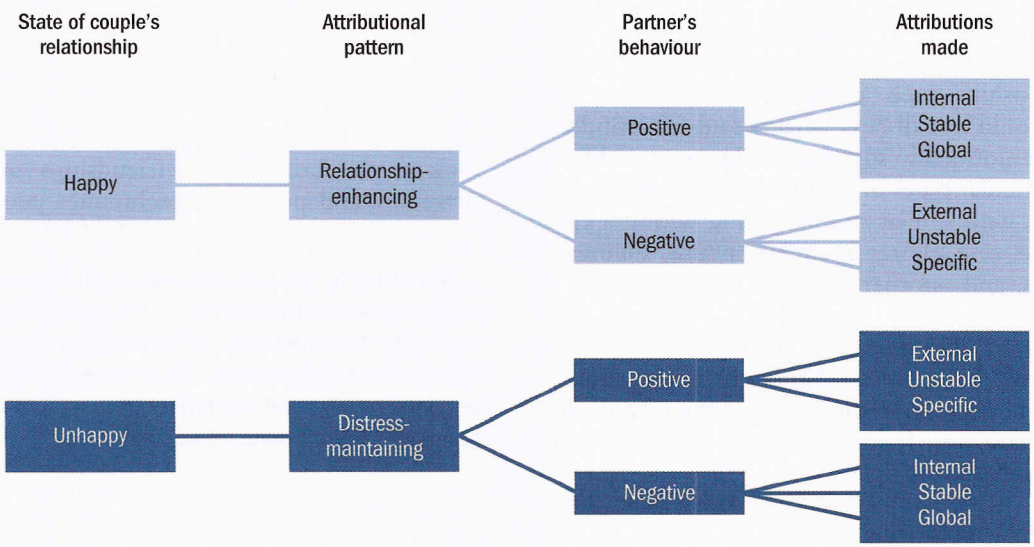

Figure 28.8 Attributions made by happy and unhappy couples according to Bradbury & Fincham (1990) (from Brehm, S.S. (1992) *Intimate Relationships* (2nd edition). New York, McGraw-Hill)

According to Bradbury & Fincham (1990), happy and unhappy couples resolve conflict in typically different ways, which can be understood as different *attributional patterns* (see Chapter 23). Happy couples use a *relationship-enhancing pattern,* while unhappy couples use a *distress-maintaining* (or *conflict-promoting*) *pattern.*

Causal attributions concern who or what produced an event, while *responsibility* attributions involves an assessment of who's accountable for the event once a cause is known. So, for example, the conflict-promoting attributional style shown in Figure 28.8 involves seeing the partner's negative behaviour as *intentional* ('you did it on purpose'), *selfish* ('you did it for what you could get out of it') and *blame* ('it's your fault') (Fincham, 2004).

According to Fincham, support for the attributional hypothesis accumulated during the 1990s. Indeed:

> ... the evidence for an association between attribution and marital satisfaction is overwhelming, making it possibly the most robust, replicable phenomenon in the study of marriage.

There's also increasing evidence that the causal link between attributions and marital satisfaction is *bidirectional*; in other words, they influence each other (Fincham, 2004). However, couples *don't* seem to have enduring attributional styles. Rather, their changing attributions over time predict their marital satisfaction, more than satisfaction predicts attributions (Karney & Bradbury, 2000).

Rule-breaking and deception

> ***ASK YOURSELF...***
> - What's the worst thing that a friend or partner could do as far as your relationship is concerned?
> - Is there anything that, *in principle,* you wouldn't tolerate?

Argyle & Henderson (1984) and Argyle *et al.* (1985) identified a number of rules thought to apply to all or most relationships, such as 'Should respect the other's privacy', 'Should not discuss what is said in confidence', 'Should be emotionally supportive'. There are additional rules for particular types of relationship. Relationships fall into clusters, with similar rules applying within a cluster. For example, one cluster includes spouse, siblings and close friends, and another includes doctor, teacher and boss.

Deception probably represents the most important rule that shouldn't be broken. Although what counts as deception will depend on the nature of the relationship, if you cannot trust your friend or partner, the relationship is almost certainly doomed.

Violation of expectations

As a relationship develops, partners learn more about each other and become increasingly close. This occurs through greater dependence on each other's activities for performance of the daily routines and fulfilment of plans and goals. As this happens, the number and strength of their *expectations* about each other increase. But, by the same token, the opportunities for *violation* of these expectations also increase. According to Berscheid & Ammazzalorso (2004):

> ... – when our partners turn out not to be the person we thought they were – we truly are endangered. The partner has become unfamiliar and thus, possibly unsafe. He or she becomes a stranger; hence, the word 'estranged' is often used to describe once close partners ... all of our customary behaviours and plans and goals that depend on the partner's behavioural contributions may be threatened.

Relationship dissolution as a process

Relationships are highly complex, and this applies to their break-up as much as it does to their formation and maintenance. It applies to the break-up of friendships and sexual relationships, and not just marriages, particularly if the relationship is a long-term one that has embraced many parts of the person's emotional, communicative, leisure and everyday life (Duck, 1988).

As we noted earlier, not all marriages involving young partners will break up while they're still young, so research needs to focus on the *processes* by which the lasting/non-lasting relationships may be distinguished (Gottman, 1994; Aldous, 1996). As Duck (1999) says:

> ... In accounting for break-up, therefore, we need to consider it as a long-term process in the lives of the partners and their associates ...

Also, people sometimes think about and plan their break-up, or maybe about how to prevent it: it doesn't always come at people 'out of the blue'. Recent research has begun to look more closely at the specific characteristics of those relationships that do break apart. What is it about the partners and their behaviour towards each other that accounts for their problems? For example, do troubled couples have particular ways of communicating and relating? (Duck, 1999). Researchers have also begun to look at the break-up of friendships, and the actions, strategies, and persuasive techniques people deliberately take to cause break-up. As Duck (1999) observes:

> ... Break-up is not just the waning of intimacy or reduction in feelings towards the partner ... the dissolution of relationships highlights the operation of relationship processes, such as interpersonal judgements, assessments of social exchange, and interactions that are present throughout a relationship but go unnoticed in routine interaction.

Duck's model

Duck's (1982) model comprises four phases, each of which is initiated when a threshold is broken.

The ending of a romantic relationship indicates that the two people are now legitimately available as partners for other relationships. This requires them to create a story for the end of the relationship that leaves them in a favourable light as potential partners. Romantic relationships are, therefore, typically ended publicly in a way that announces the ex-partners' freedom from the expectations of exclusive commitment.

Table 28.2 A sketch of the main phases of dissolving personal relationships (based on Duck, 1982, from Duck, 1988)

Breakdown–dissatisfaction with relationship
↓
Threshold: 'I can't stand this any more'
INTRAPSYCHIC PHASE
◎ Personal focus on partner's behaviour
◎ Assess adequacy of partner's role performance
◎ Depict and evaluate negative aspects of being in the relationship
◎ Consider costs of withdrawal
◎ Assess positive aspects of alternative relationships
◎ Face 'express/repress dilemma'
↓
Threshold: 'I'd be justified in withdrawing'
DYADIC PHASE
◎ Face 'confrontation/avoidance dilemma'
◎ Confront partner
◎ Negotiate in 'our relationship talks'
◎ Attempt repair and reconciliation?
◎ Assess joint costs of withdrawal or reduced intimacy
↓
Threshold: 'I mean it'
SOCIAL PHASE
◎ Negotiate post-dissolution state with partner
◎ Initiate gossip/discussion in social network
◎ Create publicly negotiable face-saving/blame-placing stories and accounts
◎ Consider and face up to implied social network effect, if any
◎ Call in intervention team
↓
Threshold: 'It's now inevitable'
GRAVE-DRESSING PHASE
◎ 'Getting over' activity
◎ Retrospective; reformative post-mortem attribution
◎ Public distribution of own version of break-up story

'Dressing the grave' involves 'erecting a tablet' that provides a credible, socially acceptable account of the life and death of the relationship. While helping to save face, it also serves to keep alive some memories and to 'justify' the original commitment to the ex-partner. As Duck (1988) puts it:

> ... Such stories are an integral and important part of the psychology of ending relationships ... By helping the person to get over the break-up they are immensely significant in preparing the person for future relationships as well as helping them out of old ones.

Duck (2001) identifies a number of classic formats for a break-up story (such as 'X suddenly changed and I had to get out'; 'X betrayed me'; 'We grew apart'). The crucial ingredients of such stories are those that show the speaker:

- is open to relationships but doesn't enter them thoughtlessly
- is aware of others' deficiencies but isn't overly critical
- is willing to work to improve a relationship or take decisive action when partners turn nasty or break the rules of relating
- is rational and sensible, and brings closure to relationships only after trauma, hard work or on reasonable grounds after real effort to make things work.

CONCLUSIONS: WHAT HAPPENS AFTER DIVORCE?

One growing area of research interest is 'postmarital' and 'remarital relationships', and family reorganisation after divorce. The increasing incidence of divorce is making blended families the norm. Indeed, there's shift in ideology, from viewing divorce as pathology to viewing it as an institution (Duck, 1999).

Once divorce is seen a common transition, rather than as pathological, researchers can reasonably begin to attend to a much wider range of issues, such as 'getting over' and prevention, and as much to the processes of entering new relationships as to those to do with leaving the old ones (Masheter, 1997: see Chapter 38).

Even the most stable and loving relationships, inevitably, dissolve. As Berscheid & Ammazzalorso (2004) say:

> ... It is one of the saddest facts of the human condition that even the closest and happiest of relationships end – if not by some circumstance of fate that causes separation, then by the death of one of the partners ...

The loss, through death, of a loved one is often accompanied by the experience of the strongest negative emotions of which human beings are capable.

CHAPTER SUMMARY

- The **need for affiliation** represents a precondition for attraction, and can be related to the need for **social comparison**. Both are enhanced under conditions of increased anxiety.

- Interpersonal relationships in western cultures tend to be **individualistic**, **voluntary** and **temporary**, whereas those in non-western cultures tend to be more **collectivist**, **involuntary** and **permanent**.
- Western psychologists tend to equate 'relationships' with 'western relationships'. This is a form of **ethnocentrism**, specifically, **Anglo-** or **Eurocentrism**.
- **Marriage** is found in all cultures. But there are important cultural variations in marital arrangements, including **monogamy**, **polygamy** (**polygyny** or **polyandry**), **mandatory marriage to specific relatives** and **arranged marriages**.
- Arranged marriages are far more common in collectivist cultures. But, even here, brides and grooms are typically given some **choice** about who they marry. Traditionally, **divorce rates** have been much lower among 'arranged couples', but these are now increasing.
- The focus on long-term heterosexual relationships has now been supplemented with discussion of **gay** and **lesbian** relationships.
- Up to the mid-1970s, psychological research into homosexuality adopted a 'pathology model'. This has been replaced by a model that emphasises the underlying **similarity** between homosexuals and heterosexuals. This approach, however, omits or distorts certain key **differences**, such as those relating to **cohabitation**, **sexual exclusivity** and **sex roles.**
- One of the most unexpected uses of the Internet is in the development of **online relationships** (**cyber affairs** or **electronic friendships**). These can be **purely virtual**, progress to increasingly sexually intense **online contact** or eventually lead to an **offline** meeting that is then maintained online.
- Berscheid and Walster distinguish between **companionate** ('true' or 'conjugal') **love** and **passionate** (romantic or obsessive) **love**. These are **qualitatively** different, but companionate love is only a more extreme form of **liking**.
- Sternberg's **triangular theory of love** comprises three basic components (**intimacy**, **passion** and **decision/commitment**), which can be combined to form different kinds of love.
- These models of love fail to take **cultural background** into account. They reflect the popular western ('Hollywood') view of the relationship between love and marriage, which *isn't* universal.
- An **evolutionary** account of love focuses on love as **attachment**. This is one of three meanings of 'I love you', the others being **love as caregiving** and **love as sexual attraction**.
- The notion of people falling in love is found in one form or another in most human societies, even where marriages are traditionally arranged by families or friends.
- Kerckhoff and Davis's '**filter model**', and other 'stage' theories, aren't strongly supported by empirical evidence. But it's generally agreed that relationships change and develop.
- A general theoretical framework for explaining **initial attraction** is that the presence of others must be **rewarding**. This can help explain the impact of **proximity**, **exposure** and **familiarity**, **physical attractiveness** and **similarity**.
- **Proximity** provides increased opportunity for interaction, which increases **familiarity** through the **mere exposure effect**. But people can become too familiar by invading our **personal space**. **Proxemic rules** dictate the appropriate distance to keep between ourselves and another person in different situations.
- **Similarity** of attitudes and values is a powerful influence on attraction, but this usually only emerges as the relationship develops. However, **physical attractiveness** is immediately apparent.
- There are important **cultural differences** in what counts as physical beauty, but there's a universal tendency for men to regard physical attractiveness as more important than women.
- The **matching hypothesis** (MH) is derived from **social exchange theory** (SET), which is a major explanation of all kinds of relationships, both intimate and non-intimate. Its different versions see people as fundamentally **selfish**, concerned only with getting as much out of a relationship as possible. But humans are capable of **altruism** as well as selfishness.
- SET is a special case of **equity theory** (ET), which adds **investment** to SET's **reward**, **cost** and **profit**. Equity refers to a **constant ratio** of profit to investment and relates to the concept of **fairness**.
- While there's little evidence for the **complementarity of psychological needs**, there's more support for complementarity in **resources**. But sociobiologists' claim that the universal male preference for physical attractiveness and female preference for financial security are genetically determined ignores cultural and historical factors.
- Marriages are more **unstable** if the couple are teenagers, from lower socio-economic groups and different demographic backgrounds, whose parents were divorced, who've been sexually active prior to marriage, and who experience early parenthood.
- **Conflict** is an inherent part of all relationships, and what's crucial is how constructively it's resolved. Happy couples tend to deal with conflict in a **relationship-enhancing way**, while unhappy couples use a **distress-maintaining pattern** of conflict resolution.
- **Rule-breaking** is a major cause of relationship breakdown, especially **deception**.
- Relationship breakdown is a **process**, involving a number of stages or phases. Research is increasingly concerned with the **aftermath** of relationship breakdown, especially divorce, and not just the breakdown itself.

Links with other topics/chapters

- Interpersonal attraction is really one aspect of *interpersonal* (or social) *perception* (Chapter 22).
- Affiliation can be understood in relation to *conformity,* especially the need to belong. We also compare ourselves with others when we're unsure what to do or think (Chapter 26).
- Ethnocentricism is a form of *bias* involved when western psychologists assume that 'relationships' and 'western relationships' are the same. Other examples of ethnocentrism are discussed in Chapter 47. That chapter also discusses cross-cultural and cultural psychology, and the differences between *cultures* (such as collectivist and individualist).
- Homosexuality is discussed in relation to definitions and classification of *psychological abnormality* in Chapter 43.
- Seeing love as a label we attach to our state of physiological arousal is consistent with the *cognitive labelling theory* of emotion discussed in Chapter 10.
- The view of romantic love as a discourse that represents a form of social control is consistent with *social constructionism* (Chapter 2).
- An evolutionary theory of love (love as attachment) is one aspect of *evolutionary psychology* (Chapter 2). Attachment is discussed fully in Chapter 32.
- The similarity-attraction principle is related to *consistency theories of attitude change* (including Heider's balance theory) (Chapter 24).
- The attractiveness stereotype is discussed, along with other aspects of *social perception,* in Chapter 22.
- Ideas about what makes people (especially women) physically attractive are relevant to discussion of eating disorders (Chapter 44).
- Analysing the factors that account for facial attractiveness is related to *facial perception* (including face recognition). This is discussed in relation to *pattern recognition* in Chapter 14.
- Sociobiological accounts of beauty are related to the *evolutionary approach* within psychology (Chapter 2). The tendency to equate beauty with youthfulness (as claimed by sociobiologists) is the flip-side of prejudice against old age (*ageism:* Chapter 39).
- The SET view of people as fundamentally selfish is relevant to discussion of *altruism and pro-social behaviour* (Chapter 30).
- Erikson's concept of intimacy is discussed as part of his *psychosocial theory* of development in Chapter 38.
- Marriage, divorce and parenthood are discussed in Chapter 37.
- Attribution is discussed in Chapter 23.
- Grief is discussed in relation to *old age* in Chapter 39.

AGGRESSION AND ANTISOCIAL BEHAVIOUR

INTRODUCTION AND OVERVIEW

Philosophers and psychologists have been interested in human aggression for a long time. According to Hobbes (1651), people are naturally competitive and hostile, interested only in their own power and gaining advantage over others. Hobbes argued that to prevent conflict and mutual destruction, people need government.

This pessimistic view of human nature was shared by Freud and Lorenz, albeit for different theoretical reasons. Like McDougall, Freud and Lorenz saw aggression as an *instinct* (see Chapter 9). In Freud's psychoanalytic theory, aggression is inherently self-destructive, but in practice is directed outwards mainly at other people, demonstrated all too clearly in the carnage of war. According to Lorenz's *ethological theory,* human beings have lost the means of controlling their aggression that other species possess, and in addition have invented weapons that allow aggression to take place from a distance.

Other explanations of aggression have combined elements of instinct theories with those of *learning theory,* such as Dollard *et al.*'s *frustration–aggression hypothesis,* and Berkowitz's *aggressive-cue theory.* Bandura's study of *observational learning's* role in aggression stimulated research into the effects of violence in the media, in particular television, and, more recently, so-called 'video nasties'. Perhaps the 'purest' social psychological account of aggression is the theory of *deindividuation.*

Baron & Richardson (1994) define antisocial behaviours as those 'which show a lack of feeling and concern for the welfare of others'. While aggression represents just one such lack of feeling and concern, it's the one that psychologists have focused on. But aggression itself can take different forms, and can be linked to motives other than wishing to harm or injure another person.

DEFINING AGGRESSION

ASK YOURSELF...
- What do you understand by 'aggression'?
- Are there different kinds of aggression?
- Is aggression the same as violence?

We all seem to recognise aggression when we witness or encounter it, but defining it often proves much more difficult. When used as a noun, aggression usually conveys some behaviour which is intended to harm another (or at least which has that effect). Yet even this definition is too broad: self-defence and unprovoked attack may both involve similar 'acts' and degrees of aggression, but only the latter would normally be considered 'antisocial' (and the law also recognises this distinction). When used as an adjective, 'aggressive' can convey that an action is carried out with energy and persistence (Lloyd *et al.*, 1984), something which may be regarded as socially desirable.

The importance of intention

Moyer (1976) and Berkowitz (1993) see aggression as always involving behaviour, either physical or symbolic, performed with the intention of harming someone. Similarly, Fiske (2004) defines aggression as entailing 'any *behaviour* whose *proximate intention* is to harm another person'. Aggressive *thoughts,* without the behaviour, *aren't* aggressive. Bushman & Anderson (2001a) distinguish between two types of intention: *proximate* (the closest and most immediate) and *primary* (*ultimate*). Aggressors operate with *multiple motives.* For example, perpetrators of school shootings may have the primary intent of revenge, suicide or fame. Terrorist attacks may have various primary intentions, such as revenge, escalating tensions, genocide, political control, moral influence, personal salvation or publicity. Domestic abuse can be motivated by control, self-enhancement, and relief from tension. According to Fiske (2004):

> ... because people's motives are complex, focusing on the most immediate, closest, or proximate goal seems more fruitful than trying to decide the primary one.

Moyer and Berkowitz reserve the word violence to describe an extreme form of aggression involving a deliberate attempt to inflict serious physical injury on another person or damage property.

Other important distinctions include:

- *hostile aggression* is aimed solely at hurting another (gratuitous aggression or 'aggression for aggression's sake'); this would exclude self-defence; it's also angry, impulsive and automatic
- *instrumental aggression* is a means to an end (and so would include self-defence: Buss, 1961; Feshbach, 1964); it's controlled and premeditated.

ASK YOURSELF...
- Can you think of any exceptions to this distinction between hostile and instrumental aggression?

Hostile aggression can sometimes be controlled, as when an angry person plots revenge over time. Conversely, instrumental aggression can sometimes be impulsive, as when a child hits another child to get its toy back. Fiske (2004) believes that examples like these make the distinction less useful.

- *Natural* or *positive* aggression is aimed largely at self-defence, or combating prejudice and other social injustice.
- *Pathological aggression* or violence results when our inner nature has become twisted or frustrated (e.g. Maslow, 1968).

THEORIES OF AGGRESSION

Instinct theories

Lorenz's ethological approach

Ethologists consider aggression to be instinctive in all species and important in the evolutionary development of the species. It allows individuals to adapt to their environments, survive in them, and successfully reproduce (see Chapter 2 and Gross *et al.*, 2000). When space or

food are scarce, many species limit their reproduction and survive by marking off living space which they defend against 'trespassers' (*territoriality*). Aggressiveness is clearly important in competing successfully for limited resources, in defending territory and for basic survival.

According to Lorenz (1966), it's legitimate to make direct comparisons between different species, although his theory of human aggression is based on the study of non-primates, and mainly non-mammals (mainly fish and insects). He defines aggression as:

... the fighting instinct in beast and man which is directed against members of the same species ...

Differences between non-human and human aggression

According to Lorenz, aggression in non-humans is basically *constructive,* but in humans it's become *distorted.*

- *Ritualisation* refers to a way of discharging aggression in a fixed, stereotyped pattern. Fights between members of the same species result in relatively little physical harm to either victor or vanquished, but at the same time allow a victor to emerge. For example, the fighting that takes place between stags is highly ritualised, and the triumphant one is the male who 'makes his point' rather than the one who kills or incapacitates his opponent. Similarly, wolves will end their fight with the loser exposing its jugular vein – but this is sufficient and no blood is spilled.

- Sometimes, antagonists may approach each other in a threatening manner - but not actually engage in combat. One will show *appeasement rituals* (or *gestures*), which prevent the other from engaging in actual conflict. For example, in one species of jackdaw, the nape section at the bottom of the head is clearly marked off from the rest of the body by its plumage and colouring. When one bird 'offers' its nape to an aggressor, the latter will never attack, even if on the verge of doing so.

ASK YOURSELF...

- Can you think of any examples of human appeasement rituals/gestures?
- How effective do you consider these to be?

Although human appeasement responses (such as smiling, cowering, cringing, or begging for mercy) are normally very effective, we've developed a *technology* of aggression. However naturally aggressive we are as a species compared with other species, our superior brains have enabled us to construct weapons which remove combat from the eye-to-eye, face-to-face situation. This inevitably reduces the overall role – and effectiveness – of appeasement rituals. Indeed, the deadliest weapons (as measured by the number of victims who can be killed or injured at one time) are the very ones which can be used at the *greatest distance* from the intended victims (such as bombs and intercontinental nuclear missiles). According to Lea (1984):

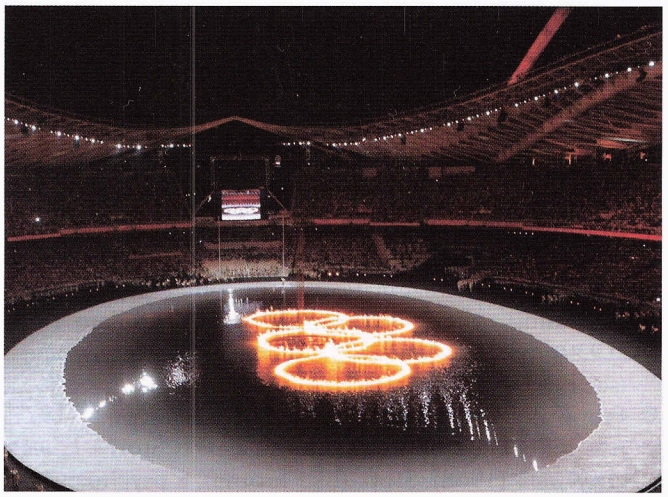
We have developed a technology which enables our intentions to override our instincts.

A passenger train destroyed in a NATO missile attack in Serbia in April, 1999, during the Kosovo conflict. At least ten people were killed and 16 others injured

An evaluation of Lorenz's theory

- In keeping with his belief that humans are naturally highly aggressive, Lorenz maintains that their 'natural condition' is that of 'warrior'. However, it's generally agreed that early human beings *weren't* warriors but 'hunter–gatherers' (such as the present-day Inuit Eskimos, Pygmies of the Ituri forest, Aborigines, Kalahari Bushmen, the Punan of Borneo, and so on), who live in small clans which hardly ever come into contact with other groups of people (Siann, 1985).
- Even without the most primitive weapons, other primates, including chimps, can and do kill each other.

Goodall (1978) describes warfare between two colonies of chimps, which ended in the killing of every male in one of the groups. Also, infanticide is one of the more common kinds of unrestrained aggression among non-human species. For example, male lions that succeed in taking over a 'pride' of females (so displacing other adult males) will often attack and kill any cubs that are present (which then makes the females available for mating). According to Lea (1984), Lorenz's claim that non-human aggression always stops before an animal is killed is basically a myth.



- Lorenz totally ignored the role of *learning* and *cultural influences,* which are far more important determinants of human aggression than biological factors. Whatever potential for aggression we may have inherited as a species, it's culturally overridden and repackaged into forms which fit current circumstances. Cultures differ in the degrees and kinds of aggression which are permissible, including gender-related aggression (see Chapter 36).
- Lorenz claims that aggression (like hunger, sexuality and flight, which collectively he calls the 'big four') isn't a response to environmental stimuli. Rather, it occurs spontaneously, when instinctive aggressive energy builds up and demands discharge (the *hydraulic model of instinct*). The evidence for this energy model is very sparse indeed (Siann, 1985), and many modern biologists and ethologists believe that aggression in animals is reactive and modifiable by a variety of internal and external conditions (Hinde, 1974).

Freud's psychoanalytic approach

As we saw in Chapter 9, Freud's theory is normally regarded as an *instinct theory.* It wasn't until late in his life that Freud recognised aggression as an instinct distinct from sexuality (libido). This change in his thinking occurred in response to the horrific carnage of the First World War. In *Beyond the Pleasure Principle* (1920) and *The Ego and the Id* (1923), he distinguished between the *life instinct* (or Eros), including sexuality, and the *death instinct* (*Thanatos*).

Thanatos represents an inborn destructiveness, directed primarily against *the self.* The aim (as with all instincts in Freud's view) is to reduce tension or excitation to a minimum and, ultimately, to eliminate it completely. This was the idyllic state we enjoyed in the womb, where our needs were met as soon as they arose, and, for a while, at our mother's breast. But after this, the only way of achieving such a *Nirvana* is through death.

Self-directed aggression, however, conflicts with the life instinct, especially the self-preservative component. But because the impulse to self-destruction is so strong, Freud believed that we must destroy some other thing or person if we're not to destroy ourselves. Conflict with the life instinct results in our aggression being *displaced* onto others. More positively, aggression can be *sublimated* into sport, physical occupations and domination and mastery of nature and the world in general. Like Freud, Lorenz also argued that we need to acknowledge our aggressiveness and to control it through sport (e.g. the Olympics), expeditions, explorations, and so on, especially if international cooperation is involved (Lorenz called these 'displacement' activities). Freud shared Lorenz's view that aggressive energy builds up until eventually it has to be discharged in some way.

Opening ceremony to the 2004 Athens Olympic Games

KEY STUDY 29.1 The overcontrolled violent criminal (Megargee, 1966)

- Megargee reported that brutally aggressive crimes are often committed by *overcontrolled* individuals. They repress their anger, and over a period of time the pressure to be aggressive builds up. Often it's an objectively trivial incident which provokes the destructive outburst. The aggressor then returns to his previously passive state, once again seeming incapable of violence.
- In Phoenix, an 11-year-old boy who stabbed his brother 34 times with a steak knife was described by all who knew him as being extremely polite and softly spoken, with no history of violent behaviour. In New York, an 18-year-old youth who confessed he'd assaulted and strangled a seven-year-old girl in a church, and later tried to burn her body in the furnace, was described in the press as an unemotional person who planned to be a minister. A 21-year-old man from Colorado accused of the rape and murder of two little girls had never been a discipline problem and, in fact, his stepfather reported, 'When he was in school the other kids would run all over him and he'd never fight back. There is just no violence in him.'
- In these cases, the homicide wasn't just one more aggressive offence in a person who'd always displayed

inadequate controls. Rather, it was a completely uncharacteristic act in a person who'd always displayed extraordinarily high levels of control. According to Megargee & Mendelsohn (1962):

... the extremely assaultive person is often a fairly mild-mannered, long-suffering individual who buries his resentment under rigid but brittle controls. Under certain circumstances he may lash out and release all his aggression in one, often disastrous, act. Afterwards he reverts to his usual overcontrolled defences. Thus he may be more of a menace than the verbally aggressive 'chip-on-the-shoulder' type who releases his aggression in small doses.

An evaluation of Freud's theory

- Despite supportive evidence such as Megargee's, Freud's ideas on aggression made little impact either on the public imagination or on other psychologists (including other psychoanalysts) until Dollard *et al.* (1939) proposed their *frustration–aggression hypothesis* (see below).
- Fromm's *The Anatomy of Human Destructiveness* (1977) was influenced by Freud's ideas, as was Storr's *Human Aggression* (1968). Storr (like Fromm, a psychoanalyst) dedicated his book to Lorenz, and in the introduction he says:

That man is an aggressive creature will hardly be disputed. With the exception of certain rodents, no other vertebrate habitually destroys members of his own species ... the extremes of 'brutal' behaviour are confined to man; and there is no parallel in nature to our savage treatment of each other ... we are the cruellest and most ruthless species that has ever walked the earth; and that, although we may recoil in horror when we read in newspaper or history book of the atrocities committed by man upon man, we know in our hearts that each one of us harbours within himself those same savage impulses which lead to murder, to torture and to war.

The frustration–aggression hypothesis (FAH)

Dollard *et al.*'s (1939) *frustration–aggression hypothesis* (FAH) was intended partly to 'translate' some of Freud's psychoanalytic concepts into learning theory terms. It claims that:

... aggression is always a consequence of frustration and, contrariwise ... the existence of frustration always leads to some form of aggression ...

While agreeing with Freud that aggression is an innate response, Dollard *et al.* argued that it would be triggered only by frustrating situations and events. Some support for this view comes from the *displacement* of aggression, as demonstrated in the *scapegoating* account of racial discrimination (see Chapter 25).

Indeed, evidence for this form of *indirect* aggression is stronger than for direct aggression (Fiske, 2004). A meta-analysis of laboratory studies found a sizeable effect of provocation on aggression towards innocent third parties when retaliation against the provoking person isn't possible (Marcus-Newhall *et al.*, 2000). Displaced aggression often focuses on a weaker, safer target than the frustrating agent. Related research into *bullying* and *partner abuse* shows that aggression towards others is an attempt to exert *control* over someone in a weaker position (Fiske, 2004).

ASK YOURSELF...

- Can you think of any exceptions to the claims made by the frustration–aggression hypothesis?
- Do we necessarily become aggressive when we're frustrated?

Some criticisms of the original FAH

Despite the evidence for displaced aggression, it soon became apparent that the FAH, in its original form, was an overstatement.

- Miller (1941) argued that frustration is an *instigator* of aggression, but situational factors (such as *learned inhibition* and *fear of retaliation*) may prevent actual aggressive behaviour from occurring. So, although frustration may make aggression more likely, it's far from being a sufficient cause of aggression.
- Bandura (1973) argued that frustration might be a source of *arousal,* but frustration-induced arousal (like other types of arousal) could have a variety of outcomes, of which aggression is only one. Whether it actually occurs is more the result of learned patterns of behaviour triggered by environmental cues.
- Frustration may also produce different responses in different people in different situations. For example, experiments seem to suggest that frustration is most likely to produce aggression if (a) the person is close to achieving his/her goal, or (b) the frustrating event seems arbitrary (Miell, 1990). Berkowitz (1993) says that if a frustration is either arbitrary or illegitimate, it's seen as unfair.

KEY STUDY 29.2 Don't frustrate me without a good reason (Kulik & Brown, 1979)

- Kulik and Brown found that frustration was more likely to produce aggression if it wasn't anticipated, and if participants believed that the person responsible for frustrating them did so deliberately and without good reason.
- This shows the importance of *cognitive factors* as cues for aggressive behaviour.
- Participants were told they could earn money by telephoning people and persuading them to make a pledge to charity. One group expected that about two-thirds of

those contacted would agree to make a pledge, while a second group expected a very low response rate. All the people telephoned were stooges, none of whom agreed to pledge.

- The first group of participants showed more aggression by slamming down the phone, speaking more aggressively, and so on. Also, those given reasonable excuses (such as 'I can't afford it') showed less aggression than those given less reasonable excuses (such as 'Charities are a waste of time and a rip-off').

The attributional perspective

ASK YOURSELF...

- How would you expect an attributional account of aggression to predict the conditions under which frustration is converted into aggression?

One of the important cognitive factors identified by Kulik & Brown is the *attribution of intention*. According to Berkowitz (1993), we aren't usually bothered by a failure to reach our goals unless we believe that the frustrater intentionally or improperly tried to interfere with our efforts. In other words, the attribution must involve a cause that's seen as *internal, controllable,* and *improper* (in violation of generally accepted rules of conduct). This is consistent with Weiner's (1986) attributional theory of emotion and motivation (see Chapter 23), and with the definition of aggression as the (perceived) intention to harm another person (see above). If there are *mitigating circumstances,* the cause may now be seen as *external* and *uncontrollable* (although still improper).

Chronically aggressive children appear to have a particular type of *attributional style.* They display a strong *hostile attributional bias* (HAB) towards seeing others as acting against them with hostile intent, especially in ambiguous situations (Nasby *et al.*, 1979). Such biased attributions often lead to *retaliatory aggression* (Taylor *et al.*, 1994).

Aggressive children make attributions rapidly and based on only some of the relevant information relating to perceived threat (Dodge & Tomlin, 1987). This suggests a state of chronic arousal and vigilance that other people experience only sporadically. The phenomenon of *excitation transfer* describes how arousal from an irrelevant prior source persists and then spills over into the next (unrelated) setting to which it's then *misattributed* (Zillman, 1988: see below). HAB also highlights the *social construction* of aggression (Mummendey, 1996: see below).

Larger frustrations may facilitate aggression because they're more likely to trigger a (perhaps biased) search for an explanation favouring a *dispositional attribution* about the frustrater. The presence of *aggressive cues* is also more likely to trigger hostile attributions (Fiske, 2004).

Aggressive-cue theory (ACT)

According to Berkowitz (1966), frustration produces *anger* rather than aggression. Frustration is psychologically painful, and anything which is psychologically (or physically) painful can lead to aggression. According to *aggressive-cue* (or *cue–arousal*) *theory* (ACT), for anger/psychological pain to be converted into actual aggression, certain cues are needed. These are environmental stimuli associated either with aggressive behaviour, or with the frustrating object or person.

Aggressive or violent behaviour is, at least partly, a reaction to specific features of the surrounding situation which 'pull out' responses that heighten the strength of the behaviour. This happens either when the environmental cues are associated in the aggressor's mind with aggression, and/or when they somehow remind the aggressor of decidedly unpleasant experiences.

Box 29.1 Berkowitz's paradigm for investigating cue-related aggression

- When participants arrive, they're told they'll be paired with another person (a stooge) in a study concerned with the physiological reactions to stress.
- To do this, they'll be asked to offer a written solution to a problem. Stress will be introduced by their solution being evaluated by their partner, who will deliver between one and ten electric shocks to them (according to his/her evaluation of the solution).
- After completing their solutions, half the participants receive a single shock, while the rest receive seven (all fairly mild), the lower number of shocks indicating a very favourable evaluation.
- Following this first stage, participants take their turn in evaluating the stooge's solution, either after seeing a violent film (*Champion,* depicting a brutal prize fight and starring Kirk Douglas), or a non-violent film (showing highlights of an exciting track race), or in the presence of objects that are/aren't associated with violence. Aggression is measured as the number of shocks the participant delivers.

Experimental tests of ACT

Berkowitz & Geen (1966) introduced the stooge to the real participant as either Bob Anderson or Kirk Anderson. As expected, the largest number of shocks was delivered by participants who were angry (had received seven shocks from the confederate), had witnessed the violent film, and believed the confederate's name was Kirk (his name was linked to the witnessed aggression through Kirk Douglas).

In a parallel experiment, the stooge was introduced either as Bob Kelly, Bob Dunne or Bob Riley: Dunne was the name of the victorious character in *Champion,* and Kelly (played by Kirk Douglas) was the loser. As predicted, the stooge received more shocks from participants who'd

seen the violent film, but most importantly, he received most shocks when he was called Kelly.

> ***ASK YOURSELF...***
> • Try to account for these findings.

In both cases (the stooge called 'Kirk' or 'Kelly' receiving the most shocks), participants encountered someone who reminded them of the victim in the witnessed aggression. He was associated with an instance of successful (i.e. rewarded) aggression, which made it more likely that anger would be converted into aggression (Berkowitz, 1993).

Berkowitz & LePage's (1967) participants were taken to a 'control room' and shown the shock apparatus. For some, there was a shotgun and a revolver on a table next to the shock apparatus, while for others there were badminton rackets and some shuttlecocks. For each participant, these objects were pushed aside by the experimenter, who said that 'they must have been left there by another experimenter'. There was a third group for whom there were no 'planted' objects. As predicted, angry participants delivered more shocks to the stooge if a shotgun and revolver were nearby (objects that, for most people, are associated with violence) than when badminton rackets were present. This is known as the *weapons effect* (see Figure 29.1).

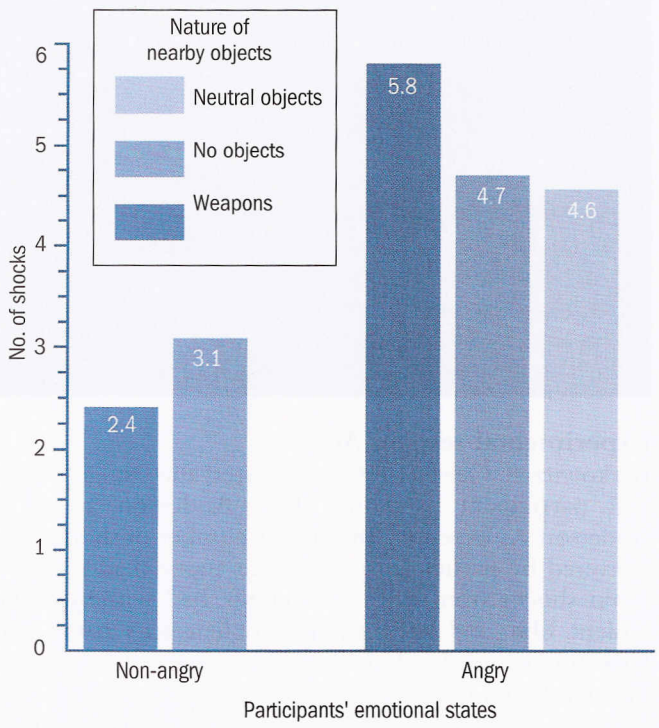


Figure 29.1 Mean number of shocks given as a function of presence of weapons (adapted from Berkowitz & LePage, 1967). (Copyright 1967 by the American Psychological Association. Adapted by permission)

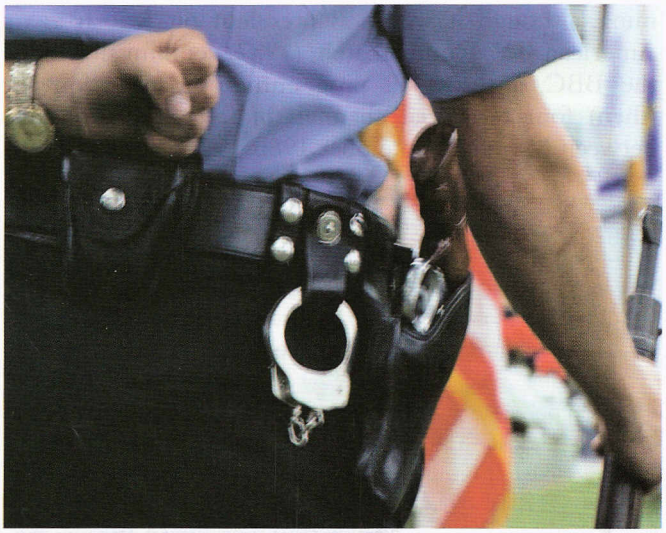
An evaluation of ACT

- These and several other similar studies seem to suggest that people's actions towards others are sometimes influenced in a relatively thoughtless, automatic way by particular details of the immediate situation. The mere physical presence of weapons, even when not used in the performance of aggressive actions, may still increase the occurrence of such behaviour. As Berkowitz (1968) put it:

> Guns not only permit violence, they can stimulate it as well. The finger pulls the trigger, but the trigger may also be pulling the finger ...



- Exposure to a weapon produces *automatic priming* (Anderson *et al.*, 1998). For example, people can identify aggression-related words faster after seeing a weapon name or picture. This suggests that weapons make aggressive thoughts more accessible. Violent media can do the same: after seeing a violent video, people list more aggressive associations to both ambiguous and non-aggressive words, as well as identifying aggressive words faster (Bushman, 1998).
- Consistent with both ACT and the weapons effect is the correlation between the availability of firearms and firearms homicide rates, both in the USA and across 16 European countries. Not only do guns make aggression more lethal when they are involved (hardly surprising), but, more surprisingly:

> ... guns also provoke aggression in their own right, simply by being there ... (Fiske, 2004)

- Apart from some failures to replicate these findings, critics have argued that participants disregarded the explanation of what the weapons and other 'props' were doing there, and realised that the experimenter expected them to be aggressive. In other words, they were responding to the *demand characteristics* of the experimental situation (see Chapter 3).
- But Berkowitz (1993) cites a study in which the more that participants believed the experimenter was interested in their aggressive responses, the *less* punitive they were towards the stooge. So, it could be that in the original Berkowitz and LePage study, the increased aggression produced by exposure to weapons occurred *despite* participants' suspicions, *not* because of their beliefs about what the experimenter expected to happen.
- Berkowitz (1995) points to a number of successful replications, including studies carried out in Belgium, Canada, Croatia, Italy and Sweden. In the Swedish study (Frodi, 1975), the weapons effect was shown by high-school boys even when they hadn't been 'angered' (i.e. shocked). According to Baron (1977):

> It is clear that Berkowitz's more general proposal that aggression is 'pulled' or elicited from without by external stimuli rather than merely 'pushed' from within has attained

widespread acceptance ... his views in this regard have been highly influential in causing social psychologists to shift their search for the determinants of aggression largely from internal conflict and motives to external environmental factors ...

Gun culture creates gun crime

Zillman's excitation-transfer theory (ETT)

According to Zillman (1982), arousal from one source can be transferred to, and energise, some other response. This is because arousal takes time to dissipate. When we're aroused, aggression may be heightened if:

- the aroused person has some disposition to react aggressively, and
- the arousal is incorrectly attributed to the aggression-provoking event rather than to the correct source.

In one test of this, Zillman and Bryant (1974) created states of arousal in participants by requiring them to ride bicycles. In some, high levels of arousal were induced, while in others low levels were induced. Participants then played a game during which they were verbally insulted by a stooge. When participants were later given the opportunity to deliver a harsh noise in headphones worn by the stooge, significantly more noise was delivered by highly aroused participants.

Box 29.2 Excitation transfer and sexual arousal

- Excitation-transfer theorists have been particularly interested in the relationship between sexual arousal and aggression (Zillman & Bryant, 1984). But the data are inconsistent.
- 'Soft' pornography apparently either decreases or has no effect on aggression, whereas 'hard-core' pornography can lead to an increase in aggressive behaviour (Donnerstein *et al.*, 1987).
- Also, sexual excitement, combined with aggressive behaviour in the sexually arousing material, has been shown to produce an increase in aggression (Donnerstein & Berkowitz, 1981).

ETT sees the relationship between arousal and aggression as a *sequence,* in which arousal is generated and then, depending on its perceived causes, labelled, producing a specific emotion such as anger (Mummendey, 1996). Berkowitz (1990), however, disputes the existence of 'unspecific' or 'neutral' arousal. According to his *cognitive–neo-associationistic approach,* anger and aggression are *parallel* rather than sequential processes, because aversive events automatically lead to the instigation of aggression, depending on what situational cues are present (Mummendey, 1996).

The social learning theory approach and media violence

Social learning theory (SLT)

According to *social learning theory* (SLT), aggressive behaviours are learned through reinforcement and the imitation of aggressive 'models' (Bandura, 1965, 1973, 1994: see Chapters 35 and 42).

Imitation is the reproduction of learning through observation (*observational learning*), and involves observing other people who serve as models for behaviour. Bandura *et al.* (1961, 1963) demonstrated how a child's aggressive tendencies can be strengthened through *vicarious reinforcement* (seeing others being rewarded for behaving aggressively).

Box 29.3 Bandura *et al.*'s procedure for investigating the effects of observed aggression

- Three-, four- and five-year-old children were exposed to an adult model behaving aggressively towards an inflated plastic 'Bobo' doll. Later, the children were allowed to play with the doll themselves. The number of acts of *imitative aggression* was the main dependent variable.
- Bandura made the important distinction between *learning* and *performance:* learning of aggressive responses (*acquisition*) doesn't necessarily mean that they'll be displayed in the child's behaviour (*performance*). In other words, a failure to imitate doesn't imply the absence of learning.
- For example, Bandura (1965) showed that when children who'd seen the model being punished for his behaviour were themselves offered *rewards* for behaving aggressively, they showed they'd learned the model's behaviours just as well as those who saw the behaviours being positively reinforced (see Key Study 35.3, page 616).

SLT and the effects of the media

SLT has contributed to our understanding of the role played by the media in both pro- (see Chapter 30) and antisocial behaviour. According to Baron (1977), the Bobo doll experiments constitute the 'first generation' (or 'phase one') of scientific research into the effects of media violence: almost all involved filmed (*symbolic*) models. The basic finding was that young children can acquire new aggressive responses not previously in their behavioural repertoire, merely through exposure to a filmed or televised model. If children could learn new ways of harming others through such experience, then mass-media portrayals of violence might be contributing, in some degree, to increased levels of violence in society (Baron, 1977).

However, Bandura himself (1965) warned against such an interpretation in the light of his distinction between learning and performance. Nevertheless, the mere *possibility* of such effects was sufficient to focus considerable public attention on his research.

There were also several methodological problems with the Bobo doll research, which made it very difficult to generalise from it to 'real world' media influence. This helped to promote 'phase two' of the study of the effects of media violence, with Berkowitz being one of the leading figures.

How much violence is there on television?

ASK YOURSELF...

- Do you believe there's a lot of violence portrayed on terrestrial TV?
- How might you measure this?
- Try to estimate the average number of violent acts (a) per programme, and (b) per hour.

The basic method of quantifying the amount of violence shown on TV involves simple counting techniques. Researchers define violence objectively, and then code samples of TV programmes for incidents matching those definitions.

Gerbner and his colleagues (Gerbner, 1972; Gerbner *et al.*, 1980, 1986; Gerbner & Gross, 1976) monitored samples of all major network prime-time and weekend daytime programmes since 1967. They defined violence as:

> ... the overt expression of physical force (with or without a weapon) against self or other, compelling action against one's will on pain of being hurt or killed, or actually hurting or killing ...

Since 1967, the percentage of TV programmes containing violent episodes has remained fairly constant, but the number of violent incidents per programme has gradually increased. In 1986, there was an average of five violent acts per hour on prime-time TV. This figure rose to 20 on children's weekend programmes (mainly cartoons).

Gerbner's analysis provided the framework for British research initiated by Halloran & Croll (1972) and the BBC's Audience Research Department. Both studies found that violence was a common feature of programming, although it wasn't as prevalent on British as on American TV. Cumberbatch (1987), commissioned by the BBC, analysed all programmes broadcast on the (then) four terrestrial channels in four separate weeks between May and September 1986.

KEY STUDY 29.3 How much violence is there on British TV? (Cumberbatch, 1987)

- Cumberbatch found that 30 per cent of programmes contained some violence, the overall frequency being 1.14 violent acts per programme and 1.68 violent acts per hour.
- Each act lasted around 25 seconds, so violence occupied just over 1 per cent of total TV time. These figures were lower if boxing and wrestling were excluded, but higher (at 1.96 violent acts per hour) if verbal threats were included.
- Perpetrators of violent acts were much more likely to be portrayed as 'baddies' than 'goodies', and violence occurred twice as frequently in law-breaking than in law-upholding contexts.

Although violence, and concerns about it, had increased in society in the decade up to 1987, this wasn't reflected by a proportional increase on TV, even in news broadcasts (Cumberbatch, 1987)

More recently, the BBC and ITV commissioned Gunter & Harrison (1998) to look at the frequency of violence on terrestrial and satellite channels.

KEY STUDY 29.4 Violence on British TV (Gunter & Harrison, 1998)

Gunter and Harrison monitored 2084 programmes on eight channels over four weeks in October 1994 and January/February 1995. The findings include that:

- on BBC 1 and 2, ITV and Channel 4, 28 per cent of programmes contained violent acts, compared with 52 per cent on Sky One, UK Gold, Sky Movies, and the Movie Channel
- violence occupied 0.61 per cent of time on the terrestrial channels and 1.53 per cent on the satellite stations
- the greatest proportion of violent acts (70 per cent) occurred in dramas and films; 19 per cent occurred in children's programmes
- most violent acts occurred in contemporary settings in inner-city locations; the majority of perpetrators were young, white males

- 1 per cent of programmes contained 19 per cent of all violent acts. *Double Impact*, shown on the Movie Channel, for example, contained 105 violent acts, as against an average of 9.7
- the USA was the most common location for violence (47 per cent), followed by the UK (12 per cent). The third most likely location was a cartoon setting (7 per cent), and then science fiction locations (4 per cent).

John Travolta and Samuel L. Jackson in *Pulp Fiction* (1994)

Gunter and Harrison (in Frean, 1995) concluded that:

> The picture that emerges is not one of a television system permeated by violence, but rather one in which violence represents only a tiny part of the output and where it tends to be concentrated principally in a relatively small number of programmes ...

An almost identical conclusion was reached by the American Academy of Paediatrics (Murray & Whitworth, 1999).

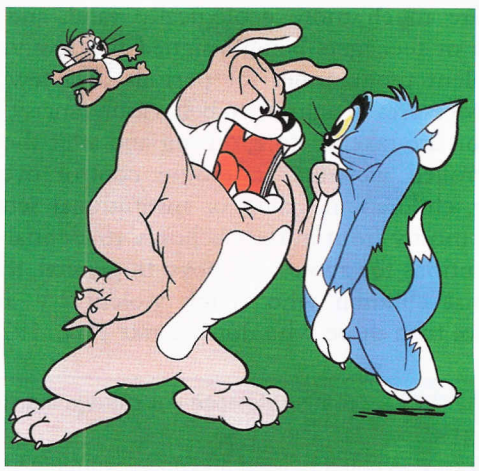
As well as TV, violent behaviour can also be seen at the cinema or on video (and what's shown may or may not be subsequently screened on TV). Evidence indicates that a large percentage of 9–11-year-olds have watched 18-rated videos, including the particularly violent *Nightmare on Elm Street, The Silence of the Lambs*, and *Pulp Fiction* (Ball & Nuki, 1996; Wark & Ball, 1996).

How much TV do people watch?

American research conducted since 1965 suggests that the time spent in a typical household in front of the TV has, in general, been steadily increasing (Burger, 1982; Liebert & Sprafkin, 1988). However, these data are typically derived from paper-and-pen surveys concerning viewing habits and may not be reliable.

Anderson *et al.* (1986) installed automated time-lapse video-recording equipment in the homes of 99 families consisting of 462 people aged between one and 62. The recordings began when the TV was switched on and stopped when it was switched off. One camera used a wide-angled lens to record people's behaviour in the room where the TV was, while a second focused on the TV screen itself. Two of their main findings were (a) no one actually watches the TV for more than 75 per cent of the time it's on, and (b) the number of hours spent looking at TV increases up to the age of 10, after which it decreases, levels off at about age 17, and continues around the same level (10 hours per week) into adulthood.

How do viewers perceive violence?



According to Gunter & McAleer (1997), viewers can be highly discriminating when it comes to portrayals of violence, and don't invariably read into TV content the same meanings researchers do. Thus, merely knowing how often certain pre-defined incidents occur in programmes doesn't tell us how significant these features are for viewers.

Viewers' perceptions of how violent TV content is, then, may not agree with objective counts of violence in programmes. According to Gunter (2000), the potential for emotional upset is increased:

- by violent portrayals in realistic settings – real-life incidents in news and documentary programmes are generally rated as being more violent than those in fictional settings
- when the violence is depicted as justified or rewarded
- when viewers strongly identify with the characters
- when the victim's pain and suffering are shown graphically.

Very young children are frightened by monsters they can see on the screen (such as *The Incredible Hulk*), while older children (9–12-year-olds) are scared by hidden evils in disguise or that lurk unseen off-camera (as in *Poltergeist*, where much of the 'horror' is covert and depends on a more sophisticated reading of story events: Gunter, 2000).

Programmes which are extremely violent according to 'objective' counts of violent acts can be seen by children as 'containing hardly any violence', and this is especially

Tom and Jerry – and friend. Evidence suggests that children see such cartoons as less violent than more realistic portrayals

true of cartoons. Subjective assessment of violence should, therefore, be incorporated into assessments of the amount of violence shown on TV (Gunter & McAleer, 1997).

Methods used to study TV violence

Correlational studies

Typically, these involve asking people which programmes they like best and which they watch most often. These data are then correlated with measures of aggression given by parents, teachers, peers, self-reports, and so on. Evidence from such studies has generally been inconsistent, but the overall amount of viewing is related to self-reports of aggressive behaviour. Of course, it's possible that those who watch violent TV are different in some way from those who don't, and the impossibility of inferring cause and effect from correlational studies weakens this methodology.

Laboratory studies

These are designed to enable the causal link between watching violent TV and behaving aggressively to be established (if it exists). Liebert & Baron (1972) randomly assigned children to two groups. One group watched *The Untouchables,* a violent TV programme, while the other watched an equally engaging and arousing, but non-violent, sports competition. Afterwards, the children were allowed to play. Those who'd watched the violent programme behaved more aggressively than the others.

The problem with laboratory studies is that most use small and unrepresentative samples which are exposed to the independent variable under highly contrived and unnatural viewing conditions. The measures of TV viewing and aggression tend to be so far removed from normal everyday behaviour that it's doubtful whether such studies have any relevance to the real world (Gunter & McAleer, 1997).

Field experiments

These are much more ecologically valid, and involve children or teenagers being assigned to view violent or non-violent programmes for periods of a few days or weeks. Measures of aggressive behaviour, fantasy, attitude, and so on are taken before, during and after the periods of controlled viewing. To ensure control over actual viewing, children in group or institutional settings are studied, mostly from nursery schools, residential schools, or institutions for adolescent boys. In general, the results show that children who watch violent TV are more aggressive than those who don't (Parke *et al.*, 1977).

KEY STUDY 29.5 Creating violence – a cottage industry? (Parke *et al.*, 1977)

- Parke *et al.* studied Belgian and American male juvenile delinquents living in small-group cottages in low-security institutions.
- Their normal rates of aggressive behaviour were assessed (using several measures of physical and verbal aggression).
- Then the boys in one cottage were exposed to five commercial films involving violence over a period of one week, while boys in another cottage saw five non-violent films during the same period.
- The former showed significant increases in aggressive behaviour for some of the categories, but increases in other measures of aggression were confined to boys who were naturally high in aggression (and who saw the violent film).

ASK YOURSELF...

- What do you consider to be the major *disadvantage* of field experiments compared with laboratory experiments?
- What particular limitations did the Parke *et al.* study have?

In field experiments, the setting cannot be controlled as well as in laboratory experiments. Consequently, we cannot be certain that the only difference between the children is the watching of either violent or non-violent TV, especially when participants aren't assigned randomly to conditions. In Parke *et al.*'s study, for example, 'cottages' (or pre-existing groups), rather than individuals, were assigned to the viewing conditions. Also, their participants (juvenile delinquent males) aren't representative of children or adolescents in general.

Natural experiments

Here, the researcher doesn't manipulate an independent variable, but takes advantage of fortuitous and naturally occurring events. Williams (1986) studied a community in Canada ('Notel'), where TV had only recently been introduced. This community was compared with one in which there was a single TV channel, and another with several channels. Verbal and physical aggression in both male and female 6–11-year-olds increased over a two-year period following the introduction of TV to 'Notel'. No such increase occurred in the communities that already had TV.

KEY STUDY 29.6 A natural experiment on the island of St Helena

- In July 1994, a study began to look at the effects of the introduction of TV to St Helena. This remote island in the south-east Atlantic has fewer than 6000 inhabitants, none of whom had ever seen live TV.
- Of its 9–12-year-olds, only 3.4 per cent had behavioural problems – the lowest ever recorded for any age range anywhere in the world. This compared with 14 per cent of children in London. Of the three- to four-year-olds, fewer

than 7 per cent had behavioural problems, compared with 12 per cent in London.

- Prior to the introduction of several 24-hour channels (including BBC World Television, MNET [a South African commercial service], and the American satellite channel, CNN), the only access the islanders had to news was on short-wave radio from the BBC World Service. While the island has three video libraries, it doesn't have a cinema.
- The study's leader, Tony Charlton, looked at the effects of the introduction of TV on 59 pre-school children, who will be monitored until they're 13, and all 800 children on the island who are of first- and middle-school age. According to Charlton:

  The children on the island represent a unique control group – it is extraordinarily difficult to find a group that doesn't have television.

- Before the study began, Charlton noted that:

  It could be that excessive viewing interferes with the development of social skills and mental capacities which children need to acquire. But there could be enormous educational benefits.

- In the fourth year of the seven-year study, prosocial behaviour (defined as helping others and playing amicably: see Chapter 30) hadn't only been maintained, but actually improved slightly.

(Based on Cooper, 1994; McIlroy, 1994; Frean, 1994; Lee, 1996; Midgley, 1998)

Longitudinal panel studies

Like experiments, but unlike correlational studies, longitudinal panel studies can say something about cause and effect, and normally use representative samples. In this case, their aim is to discover relationships that may exist or develop over time between TV viewing and behaviour. These studies, then, look at TV's cumulative influence and whether or not attitudes and behaviour are linked with watching it.

American (e.g. Lefkowitz *et al.*, 1972; Eron & Huesmann, 1985; Phillips, 1986) and British research (e.g. Sims & Gray, 1993; Bailey, 1993) shows that such a link exists. Sims and Gray, for example, reviewed an extensive body of literature linking heavy exposure to media violence and subsequent aggressive behaviour. Similarly, Bailey's study of 40 adolescent murderers and 200 young sex offenders showed repeated viewing of violent and pornographic videos to be 'a significant causal factor'. This was particularly important in adolescents who carried out abusive behaviour while they were babysitting, where videos provided 'a potential source of immediate arousal for the subsequent act', including imitating violent images.

However, some studies have failed to find such a link. Milavsky *et al.* (1982) found only small associations between exposure to violent programmes and verbal and physical aggression amongst 3200 elementary school children and adolescents. Variables such as family background, social environment, and school performance were actually much better predictors of aggressiveness, if not of actual crime (Ford, 1998).

How does television exert its effects?

Four specific effects of TV violence have been investigated. These are *arousal, disinhibition, imitation* and *desensitisation.*

- *Arousal* is a non-specific, physiological response, whose 'meaning' is defined by the viewer in terms of the type of programme being watched (Zillman, 1978). Watching TV violence increases a viewer's overall level of emotional arousal and excitement (Berkowitz, 1993). Although there doesn't seem to be any strong overall relationship between perceiving a programme as violent and verbal or physiological reports of emotional arousal (Gadow & Sprafkin, 1993; Bryant & Zillman, 1994), the more *realistic* the violence is perceived to be, the greater the reported arousal and involvement (see above, page 503).
- *Disinhibition* is the reduction of inhibitions about behaving aggressively oneself, or coming to believe that aggression is a permitted or legitimate way of solving problems or attaining goals. This relates to Berkowitz's ACT (see above).
- *Imitation* is perhaps the most direct link between watching TV and the viewer's own behaviour, and relates to Bandura's studies of imitative aggression (see page 501). However, SL theorists acknowledge the role of *cognitive factors* as mediating between stimulus and response (Bandura, 1994). How TV violence is perceived and interpreted, and the issue of realism, are clearly important *intervening variables* for both children and adults (see Box 35.7, page 617).
- *Desensitisation* is the reduction in emotional response to TV violence (and an increased acceptance of violence in real life) as a result of repeatedly viewing it. Increasingly violent programmes may be required to produce an emotional response (Gadow & Sprafkin, 1989). A study by Drabman & Thomas (1974) supports the desensitisation hypothesis. Eight-year-olds saw either a violent or a non-violent programme before witnessing a 'real' (staged) fight between two other children in a playroom. The former were less likely to tell an adult what was happening than the latter.

Reconsidering media violence

The debate about the relationship between media violence and aggression goes on. At the trial of the two boys accused of murdering two-year-old James Bulger in

February, 1993, the trial judge, Mr Justice Moreland (in Cumberbatch, 1997), said:

> It is not for me to pass judgement on their upbringing, but I suspect that exposure to violent video films may, in part, be an explanation ...

The call for legislation controlling the supply of videos to children was supported by many psychologists, including Newson (1994), whose report (*Video Violence and the Protection of Children*) was also endorsed by many psychiatrists and paediatricians.

Cumberbatch (1997), however, has questioned the validity of the evidence on which Newson's report was based. While it might be true that the father of one of the boys had rented the video *Child's Play 3* some weeks before the murder occurred (as one British tabloid claimed), his son wasn't living with him at the time, disliked horror films, and was upset by violence in videos. Similarly, it was claimed that the massacre of 16 people in Hungerford in 1987 was inspired by the murderer seeing the character 'Rambo' in the film *First Blood*. In fact, there's no evidence to support this claim (Cumberbatch, 1997).

More recently, two 14-year-old British schoolboys were convicted of attempted murder, apparently as a result of watching the film *Scream*. In the film, college students became victims of fatal knife attacks by two of their classmates. At their trial, though, the schoolboys denied that the film had influenced their behaviour (Stokes, 1999).

Cumberbatch has also criticised Comstock & Paik's (1991) conclusion that, based on Huesmann & Eron's (1986) cross-national survey in six countries (Holland, Australia, USA, Israel, Poland and Finland), viewing TV violence at an early age is a predictor of later aggression.

Box 29.4 Criticisms of the claim that viewing TV violence at an early age is a predictor of later aggression

- The Dutch researchers concluded that their results showed no effects of TV, and refused to allow their findings to be included in Huesmann and Eron's edited book of the research study.
- The Australian research showed *no* significant correlations between early TV violence viewing and later aggression.
- The American study found that when initial aggression was controlled for, the correlation between early TV viewing and later aggression was significant only in girls.
- Israeli researchers found significant effects in their city samples, but not in their kibbutz samples.
- In Poland, the researchers agreed that a greater preference for violent viewing was predictive of later aggression, but that 'the effects are not large and must be treated cautiously'.
- The Finnish researchers appeared to misunderstand their own data. Rather than showing a positive correlation between viewing violent TV and aggressive behaviour, the correlation was actually *negative*, indicating that the more TV is watched, the *less aggressive* children were later.

(Adapted from Cumberbatch, 1997)

Cumberbatch cites several other studies, which also cast doubt on claims about the connection between media violence and aggression in children.

According to Taylor *et al.* (1994):

> ... media violence is not a sufficient condition to produce aggressive behaviour, nor is it a necessary one. Aggressive behaviour is multiply determined and media violence in and of itself is unlikely to provoke such behaviour ... However ... media violence can be a contributing factor to some aggressive acts in some individuals ....

Others, however, disagree. For example, Fiske (2004) believes that:

> Research unequivocally demonstrates that media violence facilitates aggression ... review after review supports the conclusion ... The link of violent media to aggression is one of the most reliable findings in social psychology ...

Bushman & Anderson (2001b) argue that the evidence for a link is almost as strong as that between smoking and cancer, and even stronger than that between condom use and HIV prevention.

Deindividuation

ASK YOURSELF...

- Do you think people are more likely to behave in antisocial ways in a group or crowd than when they're alone?
- If so, why?

The concept of *deindividuation* has been used to try to explain why people in groups may behave in an uncharacteristically aggressive way (and in other antisocial ways), compared with their individual behaviour. When an individual's identity is lost in a mass of people, and when the markers of personality are reduced, the individual is said to be *deindividuated* (Gergen & Gergen, 1981).

Festinger *et al.* (1952) first introduced the concept of deindividuation, based on Le Bon's (1895) study of the aggressive behaviour sometimes associated with crowds. They defined deindividuation as a state of affairs in a group where members don't pay attention to other individuals as individuals and, correspondingly, the members don't feel they're being singled out by others. Belonging to a group not only provides people with a sense of identity and *belongingness* (see Maslow's hierarchy of needs – Chapter 9), but allows individuals to merge with the group, to forego individuality, and to become *anonymous*.

Empirical studies of deindividuation

While most relevant studies have been laboratory experiments, Diener *et al.* (1976) observed 1300 trick-or-treating children on Halloween night. When they wore costumes which prevented them from being recognised and went from house to house in large groups, they were more likely to steal money and candy.

Zimbardo (1969) regarded anonymity as a major source of deindividuation, and was the first to operationalise *anonymity* by having participants wear hoods and masks.

KEY STUDY 29.7 Anonymity can be bad for your health (Zimbardo, 1969)

- Female students had to deliver electric shocks to another student 'as an aid to learning'.
- Half wore bulky lab coats and hoods that hid their faces, were spoken to in groups of four, and were never referred to by name.
- The other half wore their normal clothes, were given large name tabs to wear, were introduced to each other by name, and could see each other dimly while giving the shock.
- The student who received the shock was seen through a one-way mirror and pretended to be in extreme discomfort – writhing, twisting, grimacing, and finally tearing her hand away from the strap.
- The hooded, deindividuated participants gave twice as much shock as the individuated group. If they were told that the student receiving the shock was honest, sincere and warm, she didn't receive any less shock than those believed to be conceited or critical.
- By contrast, the individuated participants *did* adjust the shock they delivered according to the victim's character.

Deindividuated participants in Zimbardo's (1969) experiment

An evaluation of deindividuation research

Manipulating anonymity hasn't always proved very easy (Brown, 1985). The participants in Zimbardo's (1969) study wore clothing resembling that worn by the Ku Klux Klan (see page 423). This uniform may have acted as a *demand characteristic* (see Chapter 3): the participants believed they should behave in a more extreme way (Johnson & Downing, 1979). In support of this, Johnson and Downing found that when participants wore surgical masks and gowns, they delivered significantly *less* electric shock than those participants whose names and identities were emphasised. This suggests that the participants' clothing and related behavioural expectations, rather than deindividuation, may have influenced their behaviour.

Similarly, in another of Zimbardo's (1969) studies, the participants were Belgian soldiers. When these soldiers wore hoods, they didn't behave more aggressively. Instead, they became self-conscious, suspicious and anxious. Their apparently individuated counterparts, who wore army-issue uniform, retained their 'normal' level of deindividuation resulting from their status as uniformed soldiers. One of the functions of uniforms in the 'real world' is to reduce individuality and hence, at least indirectly, to increase deindividuation (Brown, 1985).

Indeed, dispossessing people of their 'civilian' clothes is a major technique of *depersonalising* them in 'total institutions' such as prisons and psychiatric hospitals (Goffman, 1968, 1971). As Brown (1985) observes, the victims of aggression are often dehumanised by having their heads shaved and being dressed in ill-fitting clothes, making them appear less human. This, in turn, makes it easier for people to humiliate and abuse them.

The deindividuation produced by wearing military or police uniform increases the likelihood of the wearer's brutality. By the same token, the anonymity of massed ranks of police or soldiers may make them appear less human, making them a more obvious target for a rioting crowd's violence.

Riot police using tear-gas and batons in the protests against the World Trade Organisation in Seattle, Washington, 1999

The positive side of deindividuation

Brown (1988) refers to the US urban riots of the 1960s, where looting and violence weren't completely random but showed signs of selectivity. Similarly, the St Paul's riots in Bristol in 1984 were violent, but also relatively

controlled. Violence was aimed at specific targets (avoiding local shops and houses), and was geographically confined to a small area in the heart of the community. Far from losing their identities, the rioters seemed quite unanimous in a new sense of pride in their community produced by their activities (Brown, 1988).

Deindividuation doesn't necessarily produce antisocial behaviour. In Gergen *et al.*'s (1973) 'black room experiment', participants spent an hour together, either in a completely dark room or in a normally lit room. In the dark room, they chatted and explored the physical space to begin with, and then began to discuss serious matters. Conversation then faded and was replaced by physical contact; 90 per cent of participants deliberately touched each other. Almost 50 per cent hugged, and 80 per cent admitted to being sexually aroused. By comparison, controls talked politely in the light, for the whole hour.

It seems that we can become uninhibited in the dark, where the usual norms of intimacy no longer prevail. We feel less accountable for our behaviour in such situations, but this state of deindividuation can be to the mutual benefit of all participants (Gergen & Gergen, 1981).

The social constructionist approach

Mummendey (1996) has proposed that whether or not a behaviour is considered aggressive depends on a judgement made by either an observer or the performer. In Mummendey's view, the appraisal of a behaviour as aggressive involves going beyond a description to an *evaluation* of it. For Mummendey:

> When asking about the causes of aggression, more is of interest than simply the conditions for the occurrence of that behaviour. Of even greater importance are the conditions for judging the individual behaviour as 'aggressive'.

The case of soccer hooliganism

ASK YOURSELF...

- How might the theories of aggression discussed above explain soccer hooliganism?
- How easily can they account for the fact that most people at soccer matches *don't* behave in this way?

Marsh *et al.* (1978) used an *ethogenic* and *phenomenological* approach in their study of football hooliganism (*'The Rules of Disorder'*). This involved mainly participant observation and interviews (both formal and informal) to gather self-reports of behaviour, in an attempt to uncover the rules to which football hooligans attribute their behaviour.

Marsh *et al.* were less concerned with aggression or violence as such, and more concerned with trying to interpret the social lives of particular segments of contemporary young people. They argued that all human beings need to achieve personal dignity, a sense of self-worth and personal identity. Certain sections of young people in contemporary British society are deprived of the means of achieving these within the conventional worlds of school and work. So, they're forced to turn to the worlds of their own sub-cultures, which provide 'a sense of belonging and prestige'.

For urban *young men* in particular, it's the football terraces that allow for the emergence of sub-cultural rituals. The ritual 'warfare' between rival groups of supporters allows the construction of alternative social hierarchies, within which those who are destined to fail in conventional terms (school, work etc.) may succeed. Confrontation between rival supporters is usually *symbolic,* and consequently non-violent, as in the parading of gear (scarves, boots, denim jackets), the yelling of chants, and the chorusing of football songs. Rival fans who follow their group's rules quite carefully can avoid real physical harm to themselves or others. For example, chasing the opposition after a match ('seeing the others off') doesn't inevitably end in violence, since part of the agreed code is not actually to catch anyone.

The highly ritualised and synchronised behaviour of football supporters

Although people do get injured (and occasionally killed), all such confrontation is governed by rules. Far from being lawless, random behaviour indicating a mob's loss of control, rules exist to ensure that aggression is kept within certain bounds. Soccer hooliganism is a kind of staged production. Much of what appears to be aggression is simply part of an identity-enhancing symbolic display, a *cultural drama*. While aggression may be a taken-for-granted human predisposition, what society defines as antisocial behaviour may well be a set of functional activities dressed up as a cultural drama. According to Stainton-Rogers *et al.* (1995):

> If we look for the explanation of aggression within the individual actor, rather than addressing the complexity of the cultural

drama, we fail to recognise the social, political and economic factors which are involved in such social activity.

Marsh *et al.*'s research demonstrates one of the ways in which aggression is *socially constructed:* there are no objective 'facts' about aggression (or anything else), only accounts, interpretations, ways of talking about it, and attempts to represent it.

CONCLUSIONS

Taking the example of soccer hooliganism, violence and aggression need to be explained at several different *levels.* Most of the theories we've discussed are *individualistic.* Stemming from Le Bon's original study of rioting crowds, even deindividuation theory stresses how crowds release the primitive, uncivilised/unsocialised tendencies within the psyche of every *individual.*

What's needed is an analysis which integrates many levels of explanation. While the largely symbolic and ritualistic nature of much football supporter behaviour can be explained in terms of the 'rules' identified by Marsh *et al.*:

> ... individual or group frustrations coupled with the highly emotional atmosphere of a match may occasionally tip the balance towards real aggression. In the mix, there may also be individuals who are simply aggressive, and who find the ferment of a match an ideal context in which to indulge in overt aggression ... (Hogg & Abrams, 2000)

CHAPTER SUMMARY

- Lorenz argues that aggression between members of non-human species is characterised by **ritualisation** and **appeasement rituals/gestures**, which prevent conflict resulting in serious injury or death. In humans, these have been overridden by **destructive technology**.
- Lorenz's account seriously underestimated the extent to which members of other species kill each other, together with the role of **cultural evolution**.
- According to Freud, our self-destructive **death instinct** is 'diverted' into outwardly directed aggression. Both Freud and Lorenz believed that aggression builds up spontaneously and needs regular release. Some support for this view comes from studies of **overcontrolled violent criminals**.
- Dollard *et al.*'s **frustration–aggression hypothesis** (FAH) represented an attempt to integrate some of Freud's ideas with those of learning theory. Several modifications were made to the original theory, concerning the conditions under which frustration is likely to produce aggression.
- According to Berkowitz's **aggressive-cue theory** (ACT), environmental stimuli which have an aggressive meaning are necessary for anger to be converted into aggressive behaviour. One demonstration of this is the **weapons effect**.
- Zillman's **excitation-transfer theory** (ETT) sees the arousal–aggression relationship as a **sequence**. However, the existence of 'neutral' arousal has been questioned. The cognitive approach sees anger and aggression as **parallel** processes.
- Bandura's Bobo doll experiments were carried out in the context of his **social learning theory** (SLT), which gives central place to **observational** learning/modelling. They represent the first phase of scientific research into the effects of media violence.
- Perception of the level of **TV violence** is subjective and may not correspond with objective counts of violent incidents. Real-life incidents in news and documentaries are generally rated as more violent than those in fictional settings or cartoons.
- Several different methodologies have been used to study the effects of media violence. These include **correlational studies**, **laboratory**, **field** and **natural experiments** and **longitudinal panel studies**.
- The four specific effects of TV that have been investigated are **arousal**, **disinhibition**, **imitation**, and **desensitisation**. These have all been shown to **increase** following exposure to media violence.
- **Deindividuation** explains aggression in terms of the reduction of inhibition against antisocial behaviour when individuals are part of a group. In this setting, there's a loss of **individuality** and an increase in **anonymity**.
- Anonymity has been operationalised by wearing hoods and masks, which make it more likely that individuals will give more punitive electric shocks to an innocent person.
- However, group/crowd behaviour isn't always random, antisocial, and uncontrolled. Anonymity can reduce inhibitions to produce positive effects.
- **Social constructionists** see behaviour as being aggressive or non-aggressive if that's how it's **evaluated**. **Soccer hooliganism** may only **appear** to be violent if judged externally, and without understanding the 'rules' and rituals governing it.

ALTRUISM AND PROSOCIAL BEHAVIOUR

INTRODUCTION AND OVERVIEW

What do human kidney donors and rabbits that drum their feet on the ground have in common? At first sight, very little. But on closer inspection, they both seem to be doing things that benefit others (another person or other rabbits, respectively). In the case of the kidney donor, this is self-evident. In the case of the rabbit, drumming its feet serves as a warning to other rabbits of some threat or danger.

These are both examples of *helping behaviour*, a major form of *prosocial behaviour*. They're also often cited as cases of *altruism*, that is, help performed for the benefit of others with no expectation of personal gain. But are people – let alone rabbits – capable of acting in a purely unselfish way? Is our helping always motivated by the prospect of some benefit for ourselves – however subtle? According to Batson (2000):

> We want to know whether anyone ever, in any degree, transcends the bounds of self-interest and helps out of genuine concern for the welfare of another. We want to know whether altruism – motivation with the ultimate goal of increasing another's welfare – exists.

According to the theory of *universal egoism*, people are fundamentally selfish and altruism is an impossibility (Dovidio, 1995). This has been, and still is, the dominant ethos in social science, including psychology. Similarly, sociobiologists consider acts of *apparent* altruism to be acts of selfishness in disguise (see Gross *et al.*, 2000).

Philosophers have debated for centuries whether people are by nature selfless or selfish. McDougall (1908) proposed that 'sympathetic instincts' are responsible for altruistic acts (see Chapter 10). Only about 20 psychological studies of helping were published before 1962, but the murder of Kitty Genovese in 1964 (see below) opened up the floodgates of research into bystander intervention and altruism (Schroeder *et al.*, 1995). Latané and Darley were the pioneers of this research.

DEFINING PROSOCIAL BEHAVIOUR

According to Schroeder *et al.* (1995), *prosocial behaviour* includes behaviour intended to benefit others, such as helping, comforting, sharing, cooperating, reassuring, defending, donating to charity and showing concern. It follows that acts that *unintentionally* help others *don't* count, while those that are intended to help but actually *fail* to help *do* count.

Fiske (2004) observes that what actually *benefits* another person is socially defined, changing with time and place. Depending on the context, prosocial acts might include circumcision, foot-binding, piercing, scarring, tooth-pulling and ruthless criticism.

Although prosocial behaviours are intended to benefit others, the underlying motivation might or might not be other-oriented. The *altruism* concept underlies the subset of prosocial behaviours that are motivated mainly out of a consideration of another's needs rather than one's own (Piliavin & Charng, 1990). As a motive, altruism involves self-sacrificial costs and the absence of any 'obvious' external rewards (Batson, 1998).

What's prosocial is defined by time and place

HELPING AND BYSTANDER INTERVENTION

CASE STUDY 30.1: Kitty Genovese (adapted from the *New York Times*, March 1964)

37 Who Saw Murder Didn't Call the Police

Apathy at Stabbing of Queens Woman Shocks Inspector

By Martin Gansberg

For more than half an hour 38 respectable, law-abiding citizens in Queens watched a killer stalk and stab a woman in three separate attacks ...

Twice the sound of their voices and the sudden glow of their bedroom lights interrupted him and frightened him off. Each time he returned, sought her out and stabbed her again. Not one person telephoned the police during the assault; one witness called after the woman was dead.

'He Stabbed Me!'

She got as far as a street light in front of a bookstore before the man grabbed her. She screamed. Lights went on in the ten-storey apartment house ... which faces the bookstore.

Windows slid open and voices punctured the early morning stillness.

Miss Genovese screamed: 'Oh, my God, he stabbed me! Please help me! Please help me!'

From one of the upper windows in the apartment house, a man called down: 'Let that girl alone!'

The assailant looked up at him, shrugged and walked ... toward a white sedan parked a short distance away. Miss Genovese struggled to her feet.

Lights went out. The killer returned to Miss Genovese, now trying to make her way around the side of the building ... to her apartment. The assailant grabbed her again.

'I'm dying!' she shrieked.

'I'm dying!'

A City Bus Passed

Windows were opened again, and lights went on in many apartments. The assailant got into his car and drove away. Miss Genovese staggered to her feet. It was 3.35 a.m.

The assailant returned. By then, Miss Genovese had crawled to the back of the building ... he saw her slumped on the floor at the foot of the stairs. He stabbed her a third time – fatally.

It was 3.50 by the time the police received their first call, from a man who was a neighbour of Miss Genovese ...The man explained that he had called the police after much deliberation. He had phoned a friend ... for advice and then he had crossed the roof of the elderly woman to get her to make the call.

'I didn't want to get involved,' he sheepishly told the police.

Suspect is Arrested

Today witnesses from the neighbourhood ... find it difficult to explain why they didn't call the police.

The police said most persons had told them they had been afraid to call, but had given meaningless answers when asked what they had feared.

'We can understand the reticence of people to become involved in an area of violence,' Lieutenant Jacobs said, 'but where they are in their homes, near phones, why should they be afraid to call the police?'

... A housewife ... said, 'We thought it was a lovers' quarrel.' A husband and wife both said, 'Frankly, we were afraid.' They seemed aware of the fact that events might have been different. A distraught woman ... said, 'I didn't want my husband to get involved.'

One couple, now willing to talk about that night, said they heard the first screams ... 'We went to the window to see what was happening,' he said, 'but the light from our bedroom made it difficult to see the street.' The wife, still apprehensive, added: 'I put out the light and we were able to see better.'

Asked why they hadn't called the police, she shrugged and replied, 'I don't know.'

ASK YOURSELF...

- What do you think you'd have done if you'd been one of Kitty's neighbours?

The Kitty Genovese murder, together with findings from their laboratory studies, led Latané and Darley to introduce the concept of the *unresponsive bystander* (or *bystander apathy*) to denote people's typically uncaring attitude towards others in need of their help.

While the American media thought it remarkable that out of 38 witnesses not a single one did anything to help, Latané and Darley believed that it was precisely *because* there were so many that Kitty Genovese wasn't helped. So, how does the presence of others determine whether any particular individual will intervene in an emergency, and what other influences are involved?

The decision model of bystander intervention

According to Latané & Darley's (1970) *decision model,* before someone helps another, that person must:

- notice that something is wrong
- define it as a situation requiring help
- decide whether to take personal responsibility
- decide what kind of help to give
- implement the decision to intervene.

This represents a logical sequence of steps: a negative response at any one step means that the bystander won't intervene, and the victim won't receive help (at least not from that bystander: see Figure 30.2, page 516).

Noticing that something is wrong

Studies conducted in several different countries (including the USA, UK, Saudi Arabia and Sudan) have found that people living in urban areas tend to be less helpful than those in rural settings (Hegde & Yousif, 1992; Yousif & Korte, 1995).

ASK YOURSELF...

- Why do you think there should be this urban/rural divide?
- Does it surprise you?

Milgram (1970) believes it may represent a way in which urban dwellers cope with *stimulus overload:* they restrict their attention mainly to personally relevant events. Strangers and their situations of need may, therefore, go unnoticed.

Regardless of location, people are also more likely to be attentive to others when they're in a good mood (which, in turn, makes them more likely to help) (Dovidio & Penner, 2004).

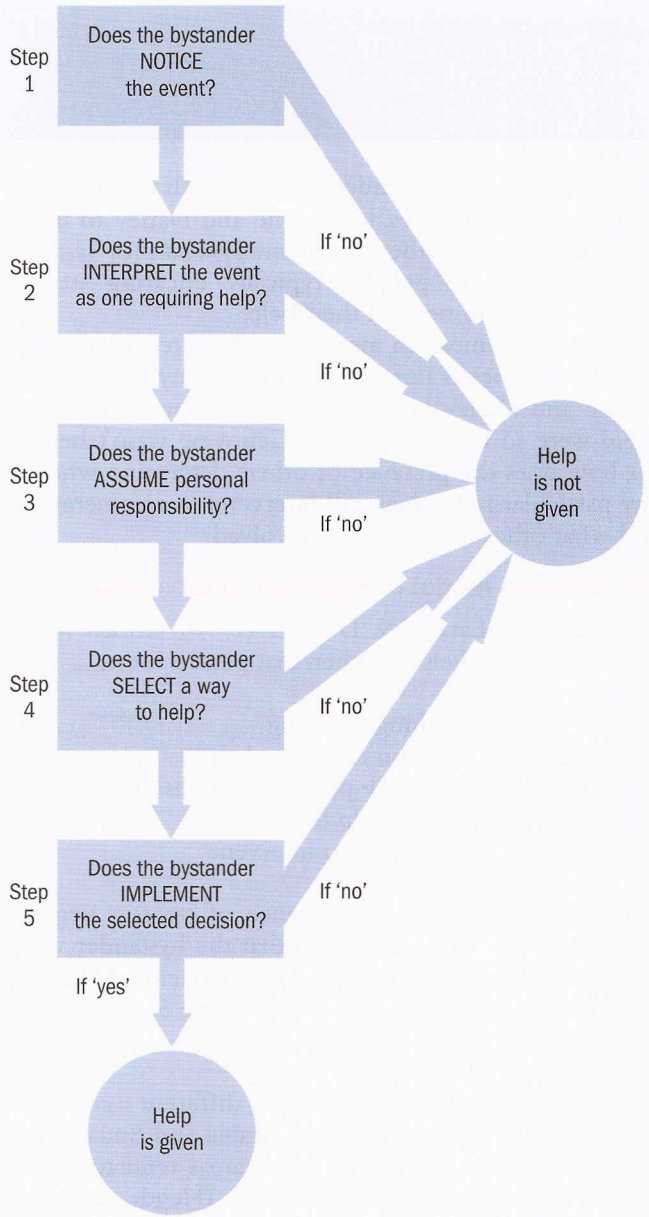

Figure 30.2 Latané and Darley's five-step decision model of bystander intervention and non-intervention (based on Schroeder *et al.*, 1995)

Defining the situation as an emergency

In one of the first bystander experiments (Latané & Darley, 1968), participants were shown into a room in order to complete some questionnaires. In one condition they were alone, while in another there were two others present. After a time, steam (resembling smoke) began to pour through a vent in the wall. 75 per cent of those working alone reported the smoke, half of them within two minutes, while 62 per cent of those in the three-person groups carried on working for the full six minutes (by which time it was difficult to see the questionnaires and the experiment was terminated).

Latané & Rodin (1969) obtained similar results when participants heard the female experimenter in an adjoining room fall, cry out, and moan. They were much faster to react when alone than when others were present. In a variation of Latané and Rodin's experiment, 70 per cent of participants on their own responded within 65 seconds, and two friends together responded within a similar time. Two strangers together were less likely to react at all (but more slowly if they did), and if someone was paired with a stooge who'd been instructed not to intervene at all, that person showed the least and slowest reaction of all.

Pluralistic ignorance

In post-experimental interviews, each participant reported feeling very hesitant about showing anxiety, so they looked to others for signs of anxiety. But since everyone was trying to appear calm, these signs weren't found and each person defined the situation as 'safe'. This is called *pluralistic ignorance.*

ASK YOURSELF...

- Can pluralistic ignorance account for the inaction of the witnesses to Kitty Genovese's murder?

There seems little doubt that the witnesses realised at the time what was going on. Although one woman claimed she thought it was a 'lovers' quarrel', most claimed they were afraid to intervene (they didn't deny that help was needed), and Kitty's second lot of screams (if not the first) must have made the nature of the situation quite unambiguous.

Genuine ambiguity may sometimes account for lack of intervention, as in situations of domestic violence. According to Shotland & Straw (1976), we'd be much more likely to help a victim if we believed s/he didn't know the attacker than if we believed a relationship existed between the two. Male participants were shown a staged fight between a man and a woman. In one condition the woman screamed 'I don't even know you', while in another, she screamed 'I don't even know why I married you!' Three times as many men intervened in the first condition as in the second condition.

Accepting personal responsibility or diffusing responsibility

KEY STUDY 30.1 The stresses of urban living (Darley & Latané, 1968)

- College students were recruited to discuss the problems of living in a high-pressure urban environment.
- Instead of face-to-face discussion, they communicated via an intercom system ('so as to avoid any embarrassment'). Each participant would talk for two minutes, then each would comment on what the others had said. The other 'participants' were, in fact, tape recordings.
- Early in the discussion, the victim (a stooge) casually mentioned that he had epilepsy and that the anxiety and

stress of urban living made him prone to seizures. Later, he became increasingly loud and incoherent, choking, gasping, and crying out before lapsing into silence.

- Darley and Latané were interested in the percentage of participants who responded within five minutes (by coming out of the small room to look for the victim).
- Of those who believed they were the *only other* participant, 85 per cent intervened. Of those who believed there were *two others* (three altogether), 62 per cent intervened, and of those who believed there were *five others* (six altogether), only 31 per cent intervened. The most responsive group was also the fastest to respond. These findings were confirmed by Latané *et al.* (1981).

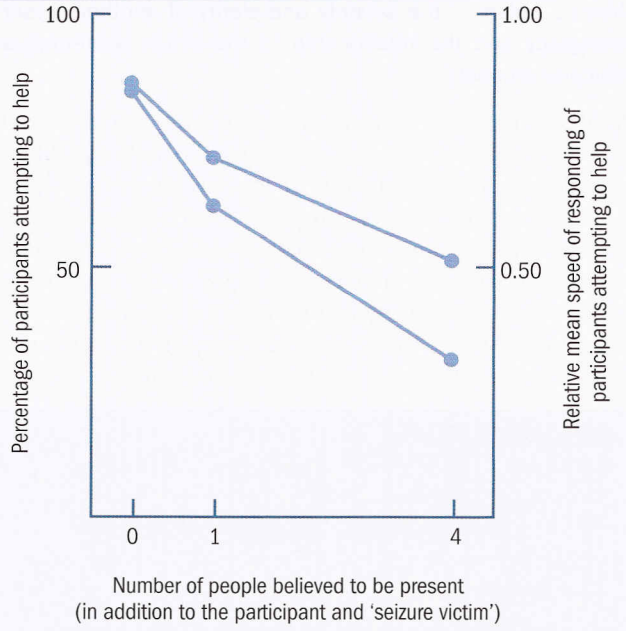

Figure 30.3 Percentage of participants attempting to help (by leaving their room to look for the 'victim' within five minutes) as a function of the number of others believed to be present, and the relative mean speed of responding of participants attempting to help (adapted from Darley & Latané, 1968)

ASK YOURSELF...

- Try to account for Darley and Latané's findings.
- Can pluralistic ignorance explain them?

While pluralistic ignorance may make it less likely that we'll define a situation as an emergency in the first place, this cannot apply in Darley and Latané's study. The best explanation is *diffusion of responsibility,* that is, the denial of personal responsibility and the belief that someone else will probably do what's necessary. The more bystanders that are present (or believed to be present), the lower the probability that any one of them will accept responsibility. This is more likely to happen when the victim is remote (can only be 'heard' from some other room in the building).

Kitty Genovese could be both heard and seen (by those who made the effort to look out of their windows), and the second lot of screams must have made it obvious that no one had gone for help!

Piliavin *et al.* (1981) use the term *dissolution* of responsibility to describe what happens when the behaviour of other witnesses cannot be observed and the participant 'rationalises' that someone else must have already intervened (as in the 'seizure' experiment). Diffusion occurs when *all* the witnesses accept responsibility. Regardless of which term is used, it's consistently found that the presence of others inhibits an individual from intervening (Pilivian *et al.*, 1981).

However, there are limits to diffusion of responsibility. Piliavin *et al.* (1969) found that help was offered on crowded subways in New York as frequently as on relatively empty ones (see Key Study 30.3). As Brown (1985) suggests, perhaps it's more difficult not to help in a face-to-face situation and in an enclosed space.

Choosing a way to help: the role of competence

Related to diffusion of responsibility, and something which may interact with it, is a bystander's competence to intervene and offer appropriate help. In the presence of others, one or more of whom you believe is better equipped to offer help, diffusion of responsibility will be increased. However, if you believe you're best equipped to help, the presence of others will have relatively little effect on your behaviour. For example, if a swimmer is in trouble, we'll usually let the lifeguard go to the rescue, and even if we were the only other person at the pool,

We're happy to diffuse responsibility when more competent bystanders are present

we'd be extremely unlikely to dive in if we couldn't swim ourselves! But if we are an excellent swimmer and are trained in life-saving skills, we'd be much more likely to help even if others were present (Baron & Byrne, 1991).

According to Schroeder *et al.* (1995), we shouldn't take the inhibiting effects of other people as necessarily indicating bystander apathy, as Latané and Darley did. People may be truly concerned about the victim's welfare, but sincerely believe that someone else is more likely – or better qualified in some way – to help. For example, Bickman (1971) replicated the 'seizure' experiment, but manipulated the participants' belief about proximity to the victim. Those who believed the other person was as close to the victim as they were (in the same building) and equally capable of helping, were less likely to help than those who believed they were alone (diffusion of responsibility). But when they believed the other person was in another building and so unable to help, they helped as much as those who believed they were alone.

Evaluation of the decision model

- Latané and Darley's model provides a valuable broad framework for understanding bystander intervention (Dovidio & Penner, 2004; Schroeder *et al.*, 1995).
- Although originally designed to explain helping in emergency situations, aspects of the model have been successfully applied to many other situations, ranging from preventing someone from drinking and driving, to deciding to donate a kidney to a relative.
- However, it doesn't provide a complete picture. For example, it doesn't tell us very much about why 'no' decisions are taken at any of the five steps, particularly after the situation has been defined as an emergency and personal responsibility has been accepted: a great deal takes place between steps 3 and 5. Also, as Dovidio (1995) points out, the model focuses on why people *don't* help others – we also need to ask why they *do*.

The arousal–cost–reward (ACR) model

The *arousal–cost–reward* (ACR) *model* (Piliavin *et al.*, 1969, 1981; Dovidio *et al.*, 1991) is a major alternative to the decision model, and represents a kind of 'fine-tuning' of some of the processes outlined in the decision model. It identifies a number of critical situational and bystander variables, which can help predict how likely it is that intervention will take place under any particular set of circumstances.

The ACR model was first introduced by Piliavin *et al.* (1969) as a 'heuristic device' in attempting to account for the results of the New York subway experiment (see Key Study 30.3). It was subsequently revised and expanded to cover both emergency and non-emergency helping (Piliavin *et al.*, 1981).

The model identifies two conceptually distinct but functionally interdependent influences on helping:

1. *arousal* in response to the need or distress of others is an emotional response. This is the basic *motivational construct*. When arousal is attributed to the distress of the victim, it's experienced as unpleasant, and the bystander is motivated to reduce it
2. the *cost–reward* component involves cognitive processes by which bystanders assess and weigh up the anticipated costs and rewards associated with both helping and not helping.

According to Dovidio *et al.* (1991):

> People are aroused by the distress of others and exhibit emotionally empathic reactions to the problems and crises of others ... also ... the severity and clarity of another person's emergency and the relationship to the victim systematically influence arousal ...

While arousal and helping are often only correlated, the ACR model sees arousal as *causing* the helping. There's considerable empirical support for this claim (Dovidio *et al.*, 1991). The model proposes that bystanders will choose the response that most rapidly and completely reduces the arousal, incurring as few costs as possible. So, the emotional component provides the motivation to do something, while the cognitive component determines what the *most efficient or effective response* will be.

> ***ASK YOURSELF...***
> - Try to remember a situation in which you helped someone who was clearly upset or distressed.
> - How did you reach the decision to help?
> - What were your motives for helping – at the time and in retrospect?

The cost–reward analysis

Research has concentrated on this part of the ACR model and, specifically, on the relative costs of helping and not helping. (But see the section on arousal below.)

- The *costs of helping* include lost time, effort, possible physical danger, embarrassment, disruption of ongoing activities, and psychological aversion (as in the case of a victim who's bleeding or drunk).
- The rewards of helping include fame, gratitude from the victim and relatives, the intrinsic pleasure and self-satisfaction derived from the act of helping, the avoidance of guilt (for not helping), and even money.
- The costs of not helping include guilt, blame from others, and cognitive and/or emotional discomfort associated with knowing that another person is suffering.

What's high cost for one person may be low cost for another (and vice versa). Cost may also differ for the same person from one situation to another, and even from one occasion to another (depending on mood, for example).

Former nursery nurse Lisa Potts shows off her George Medal for bravery, after protecting primary school children from a man wielding a machete

Table 30.1 is based largely on the ACR model as it had been proposed prior to 1981. Piliavin *et al.* (1981) and Dovidio *et al.* (1991) elaborated the model by considering the influence of a new range of variables, such as bystander personality and mood, the clarity of the emergency, victim characteristics, the relationship between the victim and potential helpers, and attributions made by potential helpers of the victim's deservingness. Many of these variables interact and contribute to (a) how aroused the bystander is, and (b) the perceived costs and rewards for direct intervention.

Different kinds of costs

Two kinds of costs associated with not helping are *personal costs* (e.g. self-blame, public disapproval) and *empathy costs* (e.g. knowing that the victim continues to suffer). According to Dovidio *et al.* (1991):

> In general ... costs for not helping affect intervention primarily when the costs for helping are low.

Although *indirect helping* becomes more likely as the costs for helping increase (as in serious emergencies), it's relatively infrequent. This may be because it's difficult for bystanders to pull themselves away from such involving situations in order to seek other people to assist (Schroeder *et al.*, 1995). The most common (and positively effective) way of resolving the *high-cost-for-helping/high-cost-for-not-helping dilemma* (see section 2 of Table 30.1) is *cognitive reinterpretation*. This can take one of three forms:

1. redefining the situation as one not requiring help
2. diffusing responsibility
3. denigrating (blaming) the victim.

Each of these has the effect of reducing the perceived costs of not helping. Schroeder *et al.* (1995) stress that cognitive reinterpretation doesn't mean that bystanders are uncaring (or 'apathetic'). On the contrary, it's the fact that they care that creates the dilemma in the first place.

The cost of time

The importance of loss of time as a motive for not helping was shown in a content analysis of answers given in response to five written traffic accident scenarios (Bierhoff *et al.*, 1987, in Bierhoff & Klein, 1988). We're

Table 30.1 Costs of helping/not helping in emergencies/non-emergencies, and the likelihood/type of intervention, as predicted by the arousal–cost–reward model (based on Piliavin *et al.*, 1969)

Costs of helping/not helping and likely outcome	**Examples**
◎ Costs of helping are low	You're unlikely to be injured yourself; the victim is only shocked.
◎ Costs of not helping are high	You'd feel guilty; other people would blame you.
Likelihood of intervention **very high – and direct**	
◎ Costs of helping are high	You don't like the sight of blood; you're unsure what to do.
◎ Costs of not helping are high	It's an emergency – the victim could die.
Likelihood of intervention **fairly high – but indirect**	Call for ambulance/police, or ask another bystander to assist.
Or **redefine the situation** (see text)	Ignore the victim and/or leave the scene.
◎ Costs of helping are high	'This drunk could turn violent or throw up over me'
◎ Costs of not helping are low	'Who'd blame me for not helping?'
Likelihood of intervention **very low**	Bystander may well turn away, change seats, walk away etc.
◎ Costs of helping are low	'It wouldn't hurt to help this blind man across the road'
◎ Costs of not helping are low	'He seems capable of looking after himself; there's very little traffic on the road'
Likelihood of intervention **fairly high**	Bystanders will vary, according to individual differences and how they perceive the norms operating in the particular situation

often in a hurry in many real-life situations, and waiting can be very frustrating. This is why the willingness to sacrifice time for a person in need can be seen as generous (time is money: Bierhoff & Klein, 1988). The most frequently mentioned motives for helping were enhancement of self-esteem and moral obligation.

KEY STUDY 30.2 If you need help, avoid a late Samaritan (Darley & Batson, 1973)

- Darley and Batson's participants were students at a theological seminary, who were instructed to present a talk in a nearby building.
- Half the students were to give a talk on the Good Samaritan, while for the other half it was about jobs most enjoyed by seminary students. Each student was then told:
  - (a) he was ahead of schedule and had plenty of time (to get to the other building), or
  - (b) he was right on schedule, or
  - (c) he was late.
- On the way to give their talk, all the students passed a man (a stooge) slumped in a doorway, coughing and groaning.
- Although the topic given for the talk had little effect on helping, time pressures did: the percentages offering help were 63, 45 and ten for conditions a, b and c, respectively.
- Ironically, on several occasions the 'late' students who were on their way to talk about the Good Samaritan literally stepped over the victim!

This experiment shows that seemingly trivial variables can exert a profound effect on altruistic responses (Bierhoff & Klein, 1988). By contrast, Bierhoff (1983) asked students to volunteer for a psychology experiment. If they participated without payment, the money would be sent to children in need. They could choose up to 12 half-hour sessions and, on average, students volunteered for 3.71 sessions. These findings indicate that the general level of helpfulness is higher than some pessimists might have assumed.

Different types of helping

Certain kinds of *casual helping* (McGuire, 1994) or *low-cost altruism* (Brown, 1986) seem to be fairly common, such as giving a stranger directions or telling them the time. Latané & Darley (1970) had psychology students approach a total of 1500 passers-by in New York to ask them such routine, low-cost favours. Depending on the nature of the favour, between 34 and 85 per cent of New Yorkers proved to be 'low-cost altruists'. However, most people refused to tell the student their names.

Generally, as the type of intervention that's required changes from casual helping through 'substantial personal helping' (such as helping someone move house) and 'emotional helping' (such as listening to a friend's personal problems) to 'emergency helping' (which is what's involved in most of the studies discussed so far), the costs of intervention increase. But so do the costs of *not* helping.

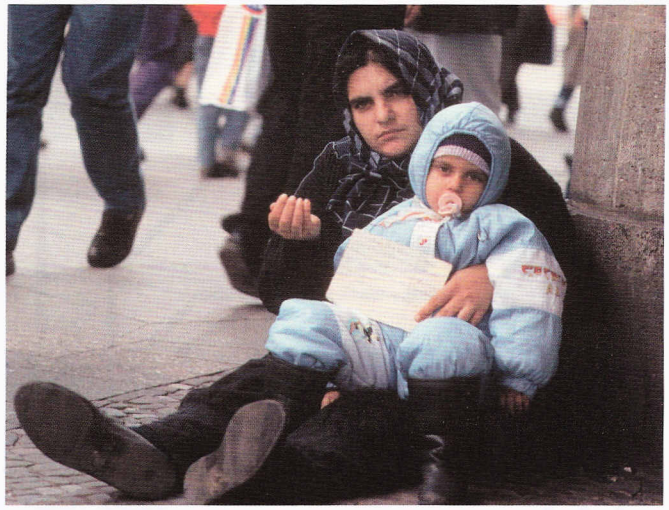
ASK YOURSELF...

- Would you be more likely to go to the aid of a stranger who collapses apparently due to the effects of alcohol or for some other (medical) reason?
- If the victim were bleeding, would you be less likely to offer help?

KEY STUDY 30.3 Good Samaritanism – an underground phenomenon? (Piliavin *et al.*, 1969)

- Student experimenters pretended to collapse in subway train compartments – they fell to the floor and waited to see if they'd be helped.
- Sometimes they were carrying a cane (the *lame condition*); sometimes they were wearing a jacket which smelled very strongly of alcohol and carried a bottle in a brown paper bag (the *drunk condition*).
- As predicted, help was offered much less often in the 'drunk' than in the 'lame' condition (20 per cent compared with 90 per cent, within 70 seconds).

Helping different kinds of victim



In a second study, the person who 'collapsed' bit off a capsule of bloodlike dye, which trickled down his chin. The helping rate dropped from 90 to 60 per cent. People were much more likely to get someone else to help, especially someone they thought would be more competent in an emergency (Piliavin & Piliavin, 1972).

Similarly, Piliavin *et al.* (1975) found that when the victim had an ugly facial birthmark, the rate of helping dropped to 61 per cent. Other studies have reported that a smartly dressed and well-groomed stranded motorist is far more likely to receive help from passing motorists than one who's casually dressed or looks untidy.

The importance of difference

The greater the victim's distress, injury or disfigurement, or the more we disapprove of them or blame their plight on their undesirable behaviour, the more likely we are to perceive them as being different from ourselves. This, in turn, makes it less likely that we'll offer them help. The psychological costs of helping someone perceived as being different from ourselves seem to be greater than the same help offered to someone perceived as being similar.

On this basis, we'd expect help to be offered less often to someone of a different racial group from the bystander. But the evidence isn't so clearcut. For example, in the New York subway experiment, there was no evidence of greater same-race helping when the victim was apparently ill. However, when he appeared drunk, blacks were

Foreign beggars on the streets of London. Are they less likely to be given money because they are foreigners – or more likely because they have children?

much more likely to help a black drunk and whites a white drunk.

ASK YOURSELF...

- How might you account for this finding in terms of different types of racism? (See Chapter 25.)

Many whites who may truly believe they're not prejudiced still harbour unconscious negative feelings. As a result of possessing both conscious, non-prejudiced convictions and unconscious, prejudiced feelings, *symbolic* (or *aversive*) racists discriminate in certain situations but not others. Where the social norms for appropriate behaviour are clear and unambiguous (for example, people who are ill should be helped), aversive racists won't discriminate. If they did behave in a discriminatory way, their self-concept (as non-racists) would be threatened, and this would mean that significant costs were incurred by not helping a victim on the grounds of race/ethnic group. However, when social norms are weak or ambiguous, or where aversive racists can justify a negative response based on some factor other than race/ethnic group ('drunks can turn nasty, so leave them alone'), then discrimination will occur.

KEY STUDY 30.4 Diffusion of responsibility as a 'cover' for racism (Gaertner & Dovidio, 1977)

- Gaertner and Dovidio used the cubicle and intercom procedure, as in the Darley & Latané (1968) 'seizure' experiment (see Key Study 30.1).
- White bystanders, who believed they were the only witness to an emergency and when appropriate behaviour was clearly defined, didn't discriminate against a black victim. In fact, they were slightly more likely to help a black than a white victim (94 per cent compared with 81 per cent).
- But when they believed there were other bystanders, they helped a black victim about half as often as a white victim (38 and 75 per cent respectively).
- The opportunity to diffuse responsibility offered a non-race-related excuse to treat blacks differently, thereby allowing them to avoid recognising racial bias as a factor (Schroeder *et al.*, 1995).

Personality differences and helping

People who are characteristically more sensitive to the needs of others might experience greater arousal in response to another's plight, or experience this arousal more negatively, or perceive greater costs for not helping. Helpers are generally more 'other-oriented' than non-helpers. Oliner & Oliner (1988) compared 231 non-Jews who helped save Jews in Nazi Europe with 126 non-savers (of similar age and nationality); the former had stronger beliefs in equality and showed greater empathy. Forty years after the Second World War ended, those who'd risked their lives were still more helpful than those who hadn't. The savers displayed both *affective empathy* (the tendency to experience emotion in response to others' emotional experience) and *cognitive empathy* (the ability to see things from another's perspective).

Oliner and Oliner also found that the savers were more likely to accept responsibility for helping. This is associated with the cognitive processes involved in weighing the various costs and rewards for helping, and the steps involved in making the decision to help (Graziano & Eisenberg, 1997). The Oliners also found that a sense of *self-efficacy* (Bandura, 1977a) and feelings of self-confidence distinguished the savers from the non-savers. These differences are related to the subjective assessment of costs and rewards, and perceptions of the ability to help successfully (Dovidio & Penner, 2004).

As Table 30.1 shows, individual differences will have their main impact when the costs for helping and not helping are both low, and when the situation is ambiguous and 'psychologically weak' or less 'evocative'. But the more emergency-like the situation (and, hence, the more compelling and evocative it is), the less relevant person variables will be. According to Dovidio & Penner (2004):

> ... although personality is now recognised as an important factor in helping, personality traits typically play a less substantial role in helping than do situational factors ...

Gender differences and helping

Although both men and women experience physiological arousal in response to others' distress, women are more likely to interpret this arousal as a positive *empathic*

response to others' needs (Eisenberg & Lennon, 1983). This would predict greater helping by women. However, Eagly & Crowley (1986) reviewed 172 studies and found that men turn out to be significantly *more* helpful than women. How can we reconcile these two things?

One answer relates traditional gender roles and the kind of helping required in most experimental studies of bystander intervention. According to Eagly (1987), the female gender role involves caring for others, providing friends with personal favours, emotional support, counselling about personal problems, and so on (*communal helping*). By contrast, the male gender role requires heroism and chivalry: men are more likely to help another when there's an audience present to witness the helping act, and/or where there's an element of risk involved in helping (*agentic helping*). Most studies of bystander intervention (at least those involving emergencies) seem to require agentic helping.

Gender roles also affect perception of the costs and rewards associated with various types of helping. For example, Otten *et al.* (1988) found that in response to friends' requests for psychological support, women (compared with men) said they'd feel worse for not visiting the friend (higher cost for not helping) and perceived the visit to be less of an imposition on their time (lower cost for helping). Similarly, men (compared with women) are more likely to see the cost of failing to act *heroically* as greater, and the cost of intervening (such as personal harm) as lower (Eagly & Crawley, 1986).

'We-ness'

According to Piliavin *et al.* (1981), this:

> ... connotes a sense of connectedness or the categorisation of another person as a member of one's own group ...

The closer the relationship to the person in need, the greater the initial arousal and costs for not helping, and the lower the costs for helping.

Evaluation of the arousal–cost–reward model

As noted in the *Introduction and overview* the crucial question as far as altruism is concerned is *why* we help other people.

ASK YOURSELF...

- Is helping ever motivated by a genuine wish to benefit someone else, or are we always motivated by self-interest?

Universal egoism

Underlying the ACR model (like exchange theory on which it's partly based) is an *economic* view of human behaviour: people are motivated to maximise rewards and minimise costs (Dovidio *et al.*, 1991). Faced with a potential helping situation, we weigh the probable costs and rewards of alternative courses of action, then arrive at a decision that produces the best outcome – *for ourselves.* This is one form of *universal egoism:* everything we do, no matter how noble and beneficial to others, is really directed towards the ultimate goal of self-benefit.

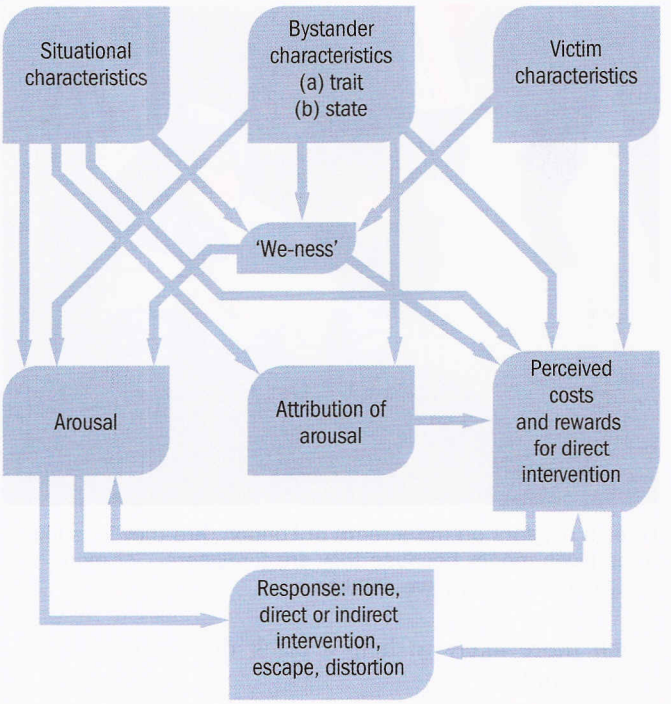


Figure 30.4 Summary diagram of influences on bystander behaviour

Another form of universal egoism relates to the *arousal* component of the ACR model. According to the *negative state relief* (NSR) *model* (Cialdini *et al.*, 1982, 1987), harming another person or witnessing another being harmed can induce negative feelings (such as guilt and sadness). This motivates the harmer/observer to reduce these feelings. Through socialisation and experience, we learn that the good feelings derived from helping can reduce these negative feelings, making us feel better. In other words, according to the NSR model, people are motivated primarily to feel good, and the motivation for helping others is essentially egoistic.

Box 30.1 Comparing the ACR and the NSR model

Although both models see helping as motivated by egoistic concerns:

- according to the ACR model, only arousal attributed to the victim's plight will motivate helping
- the NSR model maintains that *any* negative emotions (especially guilt and sadness) can motivate helping *regardless* of their attributed source
- the ACR model is a tension-reduction model, which assumes that a victim's need induces an arousal state in a potential helper, and the goal of intervention is to alleviate his/her own aversive state by removing the victim's distress

- according to the NSR model, people in negative moods are looking for ways to eliminate or neutralise their negative emotions, so *any* event will do – including those that have nothing to do with benefiting the victim.

(Based on Dovidio & Penner, 2004)

Empathy–altruism

Those who advocate the *empathy–altruism hypothesis* (EAH) (for example, Batson, 1991) don't deny that much of what we do (including what we do for others) is egoistic. But they claim that there's more than just egoism: under certain circumstances, we're capable of a qualitatively different form of motivation, whose ultimate goal is to *benefit others.*

Empathic emotions include sympathy, compassion, tenderness, and so on, and are associated with *empathic concern*. These empathic emotions can and should be distinguished from the more *self-oriented emotions* of discomfort, anxiety and upset, which are associated with *personal distress.* (This corresponds to the distinction between personal and empathic costs for not helping: see above, page 517.) While personal distress produces an egoistic desire to reduce one's own distress, empathic concern produces an altruistic desire to reduce the other's distress. These are qualitatively different responses.

According to Darley (1991):

> In the United States and perhaps in all advanced capitalistic societies, it is generally accepted that the true and basic motive for human action is self-interest. It is the primary motivation, and is the one from which other motives derive. Thus it is the only 'real' motivation, a fact that some celebrate and some bemoan but most accept ... To suggest that human actions could arise for other purposes is to court accusations of naïveté or insufficiently deep or realistic analysis ...

Testing the EAH

If helping benefits the person in need *and* the helper (as it often does), how are we to know the ultimate goal? If ultimate goals are reached by the *same* behaviour, how are we ever to know which goal or goals are ultimate? According to Batson (2000), this puzzle has led many scientists to give up on the question of the existence of altruism – it cannot be answered empirically. But Batson disagrees.

Over the past 20 years, Batson and others have conducted a series of laboratory experiments in which people are given an unexpected opportunity to help someone in need. Some are induced to feel empathy, others not. In addition, circumstances have been systematically varied in order to disentangle the altruistic ultimate goal (benefiting others) and one or more possible egoistic ultimate goals (benefiting self).

One way of teasing these goals apart is to vary the situation, so that sometimes the arousal can be reduced in a less costly way than by helping. If the ultimate goal is to reduce one's own arousal, then aroused individuals should help less when they believe they'll no longer be exposed to the person in need of help. But if the ultimate goal is to reduce the other's distress, this variation should have no effect. Several experiments using this logic have supported the EAH (Batson, 2000).

These and other experiments have led to what Piliavin & Charng (1990) call a 'paradigm shift' away from universal egoism, according to which behaviour that appears altruistic always turns out to be self-interest in disguise. This paradigm shift indicates that the dominant view of human motivation – and indeed of human nature – is wrong. As Batson (2000) says:

> ... it is not true that everything we do is directed towards the ultimate goal of benefiting ourselves. It seems that we are capable of being altruistic as well as egoistic.

But according to the *empathy-specific reward* (ESR) interpretation, people only help because they expect a reward from the victim, or from others who witnessed the act, or from themselves ('empathic joy'). But Batson *et al.* (1991) found that participants who reported high levels of empathic concern (and were, presumably, altruistically motivated) showed high levels of helping regardless of

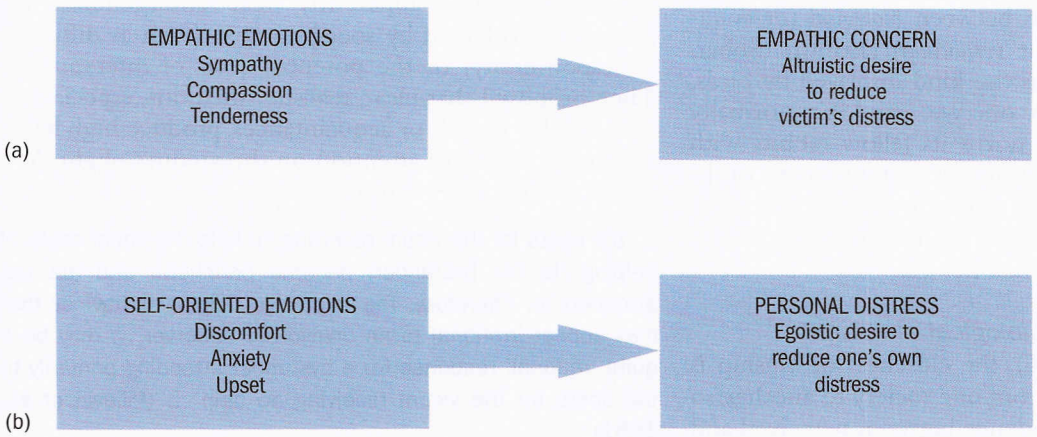

Figure 30.5 Summary of (a) the empathy–altruism hypothesis, and (b) the universal egoism account of helping behaviour

whether they'd have the opportunity to experience empathic joy. In reviewing this and other egoistic challenges to the EAH, Dovidio & Penner (2004) conclude that:

> ... the preponderance of evidence from the 20 or so years of experimentation on this question strongly suggests that truly altruistic motivation may exist and all helping is not necessarily egoistically motivated.

Universal egoism and sociobiology

If, according to universal egoists, all human acts of apparent altruism are really driven by self-interest, we might not be surprised to find a similar interpretation of the equivalent behaviours in non-human animals. There are many examples of apparently altruistic behaviour in non-humans, including the feet-drumming rabbits that we mentioned at the beginning of the chapter. This is referred to as the *paradox of altruism*.

Box 30.2 The paradox of altruism

- From a Darwinian perspective, altruistic behaviour isn't adaptive. This is because it reduces the likelihood that an individual who raises an alarm will survive: the predator is likely to be attracted to that individual.
- According to sociobiologists, this '*paradox of altruism*' can be resolved if apparently altruistic behaviour is viewed as selfish behaviour 'in disguise' (see Chapter 2).
- Sociobiologists argue that an individual animal should be seen as a set of genes, rather than a separate 'bounded organism', and that these 'selfish genes' (Dawkins, 1976) aim to secure their own survival. (See Gross *et al.*, 2000.)

Theories that explain the apparently altruistic behaviour of non-humans can, at least for sociobiologists, be applied to humans (Wilson, 1978: see Chapter 2 and Clamp, 2001).

Biological and psychological altruism

The sociobiological explanation of altruism fails to make the fundamental distinction between *biological* (or *evolutionary*) and *psychological* (or *vernacular*) altruism (Sober, 1992). Biological altruism is the kind displayed by birds, bees, ants, rabbits, and so on. We wouldn't normally attribute the rabbit which warns its fellow rabbits with altruistic motives or intentions: it's simply part of its biologically determined repertoire. Psychological altruism is displayed by higher mammals, in particular, primates and, especially, human beings.

Are humans capable of biological altruism?

According to Brown (1986), the closeness of kinship is construed very differently from one society to another, so there's no simple correspondence between perceived and actual (genetic) kinship. If altruistic behaviour directly reflected actual kinship, rather than learned conceptions of kinship, it would be impossible for adoptive parents to give their adopted children the quality of care they do.

As a species, much of our behaviour is altruistic, and as Brown says:

> Human altruism goes beyond the confines of Darwinism because human evolution is not only biological in nature but also cultural, and, indeed, in recent times primarily cultural.

Biological altruism and impulsive helping

However, biological altruism may be triggered under very specific conditions, such as a highly arousing emergency situation. People often display a rapid, almost unthinking, reflexive type of helping (*impulsive helping*) in extreme situations such as natural – and other kinds of – disasters.

Biological altruism in the 2004 tsunami disaster

Piliavin *et al.* (1981) found considerable evidence of this impulsive helping in a review of a large number of experiments involving apparently real emergencies. It's generally unaffected by social context (such as diffusion of responsibility) or the potential costs of intervention. They proposed that clear, realistic situations, especially if they involve friends or acquaintances, produce high levels of arousal and focus attention on the victim's plight. As a result, the bystander is most concerned with:

> ... the costs for the victim receiving no help. Personal costs of helping (to the bystander) become peripheral and are not attended to. Therefore, the impulsive helping behaviour that may appear irrational to an uninvolved observer ... may be a quite 'rational' response for a bystander attending primarily to the costs for the victim receiving no help ... (Piliavin *et al.*, 1981)

This description comes very close to Sober's definition of evolutionary altruism (Schroeder *et al.*, 1995). Where very close friends or loved ones are the (potential) victims, impulsive helping is even more likely to occur, because of increased arousal and sensitivity to the other's distress (Clark *et al.*, 1989).

So, both sophisticated reasoning (as in psychological altruism) and more primitive, non-cognitive, biological mechanisms may permit humans to perform a range of altruistic behaviours well beyond those of other species. According to Schroeder *et al.* (1995):

> We may well indeed be a uniquely compassionate and altruistic beast ... altruism may be both a behaviour that has evolved because it is vital to the survival of humanity and a behaviour that is learned and reinforced by most societies because it is vital to the survival of their culture.

THE MEDIA AND PROSOCIAL BEHAVIOUR

Television and prosocial behaviour

If television can have harmful effects as a result of watching antisocial behaviour (see Chapter 29) then, presumably, it can have beneficial effects by promoting prosocial behaviour. According to Gunter & McAleer (1997):

> Concern about the possible antisocial influences of television far outweighs the consideration given to any other area of children's involvement with television ... Television programmes contain many examples of good behaviour, of people acting kindly and with generosity. It is equally logical to assume that these portrayals provide models for children to copy.

Box 30.3 Evidence for the prosocial effects of TV

- **Laboratory studies with specially produced instructional film or video materials:** Specially prepared materials have been shown to influence courage, the delay of gratification, adherence to rules, charitable behaviour, friendliness, and affectionate behaviour.
- **Laboratory studies with educational broadcasts specially produced for social skills teaching purposes:** TV productions designed to enhance the social maturity and responsibility of young viewers include *Sesame Street* and *Mister Roger's Neighborhood*. Children who watch these programmes are able to identify and remember the cooperative and helping behaviours emphasised in certain segments.
- **Laboratory studies with episodes from popular TV series:** Specially manufactured TV programmes or film clips influence children's prosocial tendencies, at least when the prosocial behaviour portrayed is very similar to that requested of the child. But there's only limited evidence that ordinary broadcast material can enhance a wide range of helping behaviours.
- **Field studies relating amount of viewing of prosocial TV content to strength of prosocial behaviour tendencies:** Children who watch little TV, but watch a lot of programmes with high levels of prosocial content, are more likely than others to behave prosocially. But the correlations between viewing habits and prosocial behaviour are lower than those between viewing habits and antisocial behaviour.

  In part, this may be because prosocial behaviours are verbally mediated and often subtle, whereas antisocial behaviours are blatant and physical. Children learn better from simple, direct and active presentation, and so aggressive behaviours may be more readily learned. Also, the characters who display prosocial behaviour (typically female and non-white) and antisocial behaviour (typically male and white) may confound the relative influence of prosocial and antisocial behaviours with the types of character that portray them.

(From Gunter & McAleer, 1997; Gunter, 1998)

Television violence and catharsis

ASK YOURSELF...

- How might Freud's and Lorenz's theories of aggression explain the benefits of watching TV violence (see Chapter 29)?

One positive effect of TV might be that witnessing others behaving aggressively helps viewers to get their aggressive feelings 'out of their systems', and hence be less likely to behave aggressively. The claim that TV can act as a form of *vicarious catharsis* is based partly on Freud's and Lorenz's theories of aggression.

However, the evidence doesn't support the view that TV is cathartic for everybody. If a discharge of hostile feelings occurs at all, it's probably restricted to people of a particular personality type, or those who score high on cognitive measures of fantasy, daydreaming and imagination (Singer, 1989). Only for some people does TV violence have positive effects and provide a means of reducing aggressive feelings (Gunter & McAleer, 1990).

Computer games: good or bad?

Antisocial behaviour

According to Griffiths (1998), little is known about the long-term effects of playing violent computer games. However, great concern has been voiced that such games may have a more adverse effect on children than TV, because of the child's active involvement (Keegan, 1999). Griffiths's review of research indicates that the effects of long-term exposure to computer games on subsequent aggressive behaviour 'are at best speculative'.

However, recent research by Colwell (in Leake, 2000) claims that violent computer games are strongly linked with aggression in teenage boys, and that they're increasingly becoming substitutes for friendship. Colwell's study of 204 12–14-year-olds in London claims to have shown a causal link between playing violent games and aggressive behaviour.

Prosocial behaviour

As far as prosocial behaviour is concerned, computer games:

- give children access to 'state of the art' technology, a sense of confidence, and equip them with computer-related skills for the future (Surrey, 1982)
- may also promote *social interaction;* Mitchell (1983, in Griffiths, 1993) found that families generally viewed computer games as promoting interaction in a beneficial way through cooperation and competition
- may be cathartic in that they allow players to release their stress and aggression in a non-destructive way, and relax them (Kestenbaum & Weinstein, 1985). Other benefits include enhancing cognitive skills, a sense of mastery, control and accomplishment, and a reduction in other youth problems due to 'addictive interest'(!) in video games (Anderson & Ford, 1986).

According to Griffiths (1997a), there appear to be some genuine applied aspects of computer game-playing. But he notes that many of the assertions made above were subjectively formulated, and not based on empirical research findings.

CONCLUSIONS

In March 1984, the Catherine (Kitty) Genovese Memorial Conference on Bad Samaritanism was held. Experts shared what they had learned in the 20 years since her murder. The *New York Times* again reported on the conference:

> It's held the imagination because looking at those 38 people, we were really looking at ourselves. We might not have done anything either. That's the ugly side of human nature. [O'Connor, law professor]

> The case touched on a fundamental issue of the human condition, our primordial nightmare. If we need help, will those around us stand around and let us be destroyed or will they come to our aid? Are those other creatures out there to help us sustain our life and values or are we individual flecks of dust just floating around in a vacuum? [Milgram, psychology professor]

According to Dovidio & Penner (2004):

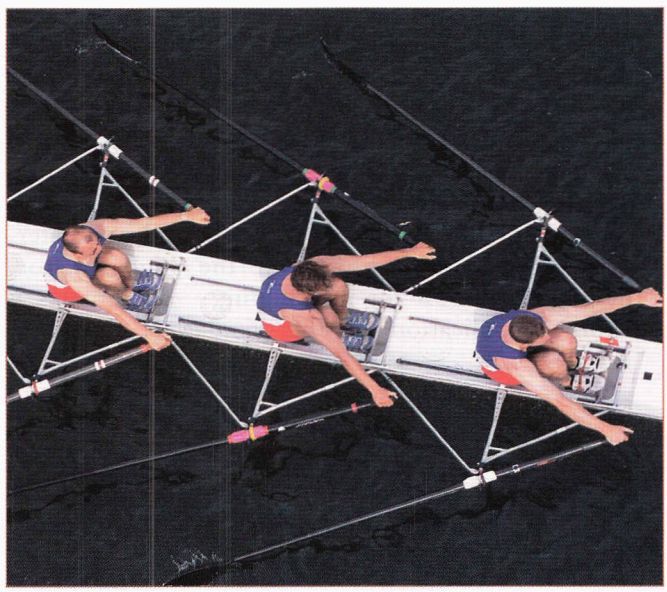
> ... helping is a complex multidimensional behaviour. Whether it is spontaneous and short-term or planned and sustained, helping is an evolutionarily important behaviour that is shaped by fundamental cognitive and affective processes, involves self- and other-directed motives, and has consequences that are central to one's self-image and social relationships ...

CHAPTER SUMMARY

- **Helping** as a form of **prosocial behaviour** has been studied largely in the form of **bystander intervention**. The murder of Kitty Genovese, together with early laboratory experiments, led Latané and Darley to introduce the concept of the **unresponsive bystander/bystander apathy**.
- According to Latané and Darley's **decision model**, a bystander will pass through a logical series of steps before actually offering any help. A negative decision at any step leads to non-intervention.
- The more potential helpers there are (believed to be) present, the more likely it is that **diffusion** (or '**dissolution**') **of responsibility** will take place.
- How **competent** we feel to offer appropriate help will influence diffusion of responsibility. This suggests that diffusion of responsibility *doesn't* imply apathy about what happens to the victim.
- The decision model emphasises only why people don't help, rather than why they do. The **arousal–cost–reward** (ACR) **model** is an extension of the decision model, identifying a number of critical **situational** and **bystander variables**, which help predict the likelihood of helping under particular circumstances.
- **Arousal** constitutes the **motivational** part of the model, while **cost–reward** involves the **cognitive** weighing-up of anticipated costs and rewards for both helping and not helping.
- The most common solutions to the **high-cost-for-helping/high-cost-for-not-helping dilemma** are **re-defining the situation**, **diffusing responsibility** and **blaming the victim**. These are all forms of **cognitive reinterpretation.**
- The costs of helping and not helping differ according to the **type of help required, victim characteristics** (including perceived similarity to the bystander), **bystander personality** and **gender**, and the **bystander–victim relationship**.
- Helping can be called **altruism** only if the motive is to benefit the victim (**empathic concern**). According to the **empathy–altruism hypothesis** (EAH), human beings are capable of altruistic acts, but according to **universal egoism**, helping is always motivated by **personal distress**.
- According to the **negative state relief (NSR) model**, people are motivated to help others in need by their own egoistic need to reduce/remove their state of negative arousal caused originally by the victim's plight.

- While non-humans are incapable of **psychological altruism**, humans are capable of **biological altruism** (impulsive helping), triggered by highly arousing emergency situations, especially where friends or relatives are involved.
- **Field studies** indicate that the amount of **prosocial TV content** viewed is related to the strength of **prosocial behaviour**. But this relationship is weaker than that between viewing habits and antisocial behaviour. This may be because antisocial behaviours are learnt more easily than verbal and subtle prosocial behaviours.
- Little is known about the long-term effects of playing **violent computer games**, but the child's active involvement makes them potentially more harmful than TV.
- The **benefits** of computer games could include providing an opportunity for **releasing stress** and **aggression** in a non-destructive way.

Links with other topics/chapters



- The cost–reward component of the ACR model corresponds to the *exchange theory explanation of intimate relationships* (Chapter 28) (The arousal component is what distinguishes the ACR model from exchange theory.)
- Denigrating the victim (as a form of cognitive reinterpretation when dealing with the high-cost-for-helping/high-cost-for-not-helping dilemma) is another application of the *'just world' hypothesis* (Chapter 23).
- The three forms of cognitive reinterpretation could also be seen as *rationalisations* that reduce the bystander's *cognitive* dissonance (Chapter 24).
- Graziano & Eisenberg (1997) identify individual differences in empathy as one kind of evidence supporting the claim that personality traits can account for variance in prosocial behaviour. This complements Eisenberg's research into the *development of prosocial moral reasoning* (Chapter 35).
- *Self-efficacy* (as a personality characteristic that can make some people more likely to act prosocially than others) is also relevant to (a) Bandura's (1986, 1989) *social cognition theory of moral development* (Chapter 35), and (b) Bandura's (1977a) account of why *psychotherapy* works (*process research*) (Chapter 45).
- Typical differences between male and female helping are related to Gilligan's (1982) research into differences in their *morality/moral reasoning* (Chapter 35).
- The ACR model maintains that only arousal attributed to the victim's plight will motivate helping. This is especially relevant to Weiner's *attributional theory of motivation* (Chapter 23), as is the attribution of responsibility ('Is it the victim's own fault?'). It also relates to Schachter's *cognitive labelling theory of emotion* (Chapter 10).
- The finding that impulsive helping is more likely in the case of close friends or loved ones can be (partly) explained in terms of *familiarity* (Chapter 28) and *attachments* (Chapter 32).
- Research into the harmful effects of violent computer games, and the prosocial effects of TV, complement research into the link between *watching violent TV/movies* and *aggressive behaviour* (Chapter 29).

APPLICATION

THE SOCIAL PSYCHOLOGY OF SPORT

INTRODUCTION AND OVERVIEW

As we saw in Chapter 30, sociobiologists believe that an individual animal should be seen as a set of genes, and that these *selfish genes* (Dawkins. 1976) aim to secure their own survival. This view of evolution implies that there's no such thing as society: sociobiologists have ridiculed the idea that *groups* of organisms might gain a survival advantage over other groups because they shared some beneficial trait.

However, biologists are starting to understand that evolution takes place on a variety of levels (Dicks, 2000). Natural selection may favour certain genes, but it can also favour particular societies. Provided a group of individuals can cooperate without any cheats trying to sneak an unfair advantage, then it may evolve as a single unit. Indeed, Darwin's solution to the *paradox of altruism* was to suggest that natural selection operates among groups of organisms (see Chapter 30). As Dicks puts it:

> A group of people who are kind and helpful to each other may not do so well individually, but as a team they may do better than other groups of people, and so the tendency to work as a team spreads through the population.

While not all sport is team sport, of course, applications of social psychology to sport tend to focus on *group processes* (see Chapter 26), such as *social facilitation*, factors affecting group performance (such as *social loafing*), and *group cohesion*.

WHAT IS SPORT PSYCHOLOGY?

Walley & Westbury (1996) define sport psychology as the:

> ... scientific study of human behaviour and experience in sport (where ... 'sport' is used to cover various levels of recreational activities, competitive sports, and health-oriented exercise programmes) ...

Triplett's (1898) study of social facilitation (see below) is often cited as the first experiment in social psychology, but on closer inspection it had stronger links with psychophysiology and sport psychology (Hogg & Vaughan, 1998). Indeed, sport psychology is generally seen as having started with Triplett's study (Hardy, 1989). But it first became recognised as an academic discipline in the UK in the late 1960s, going from strength to strength since the early 1980s, with the psychology content of sports science degrees gradually increasing. However, it wasn't until 1992 that the British Psychological Society acknowledged sport psychology by forming an interest group. A fully fledged Sport and Exercise Psychology Section was established in 1993. The aim is for this to become a Division (Cockerill, 2002).

The British Association of Sports Sciences has set up a register of sport psychologists. To become registered, sport psychologists are normally expected to have a first degree in sports science and a higher degree in psychology – or vice versa. Many sports-governing bodies require trainee coaches to attend short courses and workshops aimed at increasing awareness of the importance of sport psychology. These courses are coordinated by the National Coaching Foundation.

ASK YOURSELF...

- What do you think sport psychologists do?

The scope of sport psychology (SP)

According to Walley & Westbury (1996):

> The image that many people have of a sport psychologist is someone who comes in to 'psych up' players before a game, the purpose being to make them more competitive or even aggressive ...

They believe this image is very misleading.

Box 31.1 Different areas of work involving sport psychologists

Clinical sport psychology: Trained clinical psychologists (see Chapter 1) deal with performers' emotional and behavioural problems. Several Olympic-standard US and British performers have been successfully treated for a range of problems, including acute anxiety, eating disorders, depression, and obsessive–compulsive behaviour (see Chapter 44).

Research sport psychology: This is a largely applied area of research, concerned with real-life problems confronting coaches and players. Researchers also try to ensure that their findings are made available not just to the academic community, but also to coaches, athletes, and teachers. Some of the issues addressed are how stress affects performance, what factors affect performers' decision to drop out of sport, and how complex skills are learned and controlled.

Education sport psychology: This aims to teach participants in sport mental skills which will enhance both their performance in, and enjoyment of, sport. Sport psychologists may be consulted on:

- how to manage performance-related stress and anxiety
- how to increase and maintain self-confidence
- how to use mental rehearsal to facilitate learning of skills
- team-building
- coach education.

British SP reflects international trends. Some additional research areas include the following.

- Identification of factors that determine peak performance, such as stress (see Chapter 12), motivation (see Chapter 9), and mental preparation. The role of stress in athletic performance grew out of the early interest in social facilitation (see below). According to Hardy (1989):

  > Competitive athletes ... may represent an invaluable microcosm within which we may test and refine our understanding of human adaptation. The athlete must learn to cope with a wide range of stressors – performance standards, the experience of failure, ageing and so on. In evaluating our theories and developing new treatment techniques, the athlete may, therefore, be an able and willing ally ...

- Skill development (including in children and performers with special needs).
- Psychological effects of participation in sport, and exercise and sport as a means of promoting health.
- Identification of personality factors underlying elite performance and attraction to different sports (very popular in the late 1960s and early 1970s: see Chapter 42).

Zuckerman's (1979) *sensation-seeking scale* has attracted quite a lot of attention and has been successful in predicting leisure preferences and participation. The high sensation-seeker displays a need for varied, novel sensations, and appears willing to take physical and social risks to gain these experiences (Furnham & Heaven, 1999). As predicted by Zuckerman's scale, white-water canoeists and kayak paddlers showed higher than average scores (especially on the thrill and adventure-seeking sub-scales: Campbell *et al.*, 1993). Also, athletes scored higher than non-athletes, contact sports athletes scored higher than non-contact sports athletes, and male athletes scored higher than female athletes (Schroth, 1995).

Box 31.2 T types and the adrenaline rush

- *Type T* (for 'thrill') *personalities* thrive on taking risks (Farley, in Schueller, 2000b).
- The most visible members of the type T group today are the extreme athletes, such as the hang-gliders, bungee jumpers, and those who jump off tall buildings. For example, Kristen Ulmer considers herself to be a full-time 'adrenaline sports' athlete. As well as being voted the craziest skier in North America, she rock climbs, paraglides, and dabbles in ice climbing and mountain biking.

- But Farley believes that you can get an adrenaline rush without jumping off a building or hang-gliding. It can come from sex or gambling (see Chapter 8), and those who push the frontiers of the mind rather than the body are also thrill-seekers. Adrenaline surges have been recorded during chess tournaments, and Farley cites Einstein as a mental T type. Type Ts need to push their abilities –physical or intellectual – to the limits.
- What makes a type T may be at least partly due to 'thrill-seeking' genes, which affect dopamine receptors in the brain (see Chapter 4).
- Farley believes that human progress demands risk-taking. There's a very simple motive underlying creativity, risk-taking, exploring, and adventure; namely, thrill.

(Based on Schueller, 2000b)

According to Moran (2000), the traditional role of the sport psychologist as expert is giving way to a new model for the delivery of sport psychological services:

> ... this model identifies the coach rather than the athlete as the primary target for psychological education. Accordingly, the role of the sport psychologist changes from that of a medical expert to that of a management consultant – somebody who works as part of a team with the coach/manager and the support staff ...

Of course, this model doesn't eliminate the need for individual consultation; there'll always be situations which warrant one-to-one interactions between athletes and sport psychologists. But for Moran:

> ... what does change in this new approach is the expectation that sport psychologists are 'mind-benders' who provide some arcane expertise to athletes who are beyond the help of their coaches ...

It's only when such myths are dispelled that either theoretical or practical progress in SP is possible.

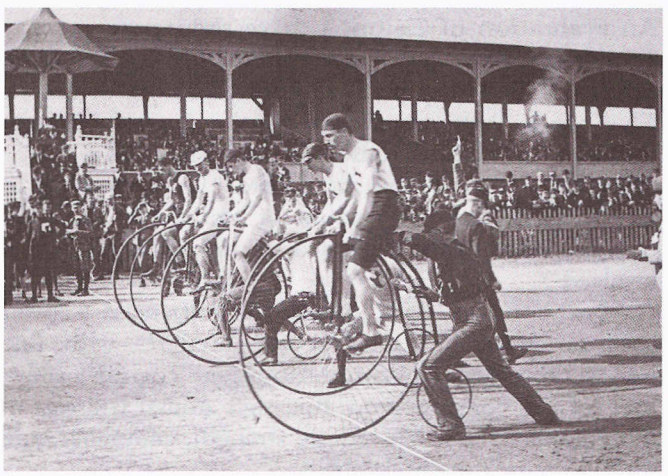
The status of sport psychology

According to Woods (2001), SP is now a recognised academic discipline, but exactly where it belongs is a matter of debate. She identifies two major views of its role.

1. According to one view, SP is a *sub-discipline of mainstream psychology,* based on its theories, models and research methods. But sport psychologists have found it difficult applying mainstream ideas to the reality of the sport setting. As a result, for the last 20 years or so research has moved increasingly towards a focus on the experiences of athletes themselves. This has revealed fascinating material on competitive anxiety, self-efficacy, how anxiety and arousal interact in competition, and 'home team' advantage.
2. This more recent research is related to the second view of SP as a *sub-discipline of sport science* (which also includes motor skills, biomechanics and nutrition). The inclusion of SP would strengthen the inter-relationship between sports-related topics, and could promote the development of research hypotheses and methods appropriate to the sport setting.

Athletes and coaches at all levels are becoming increasingly aware that to enjoy the benefits sport has to offer:

> ... success does not only depend on a sound technique and being fit enough to execute the skills that have been learned. It also relies upon the acquisition of certain psychological skills, such as motivation and commitment, being able to perform under pressure, coping with adversity, effective organisation, and many others ... (Cockerill, 2002)



However, Cockerill believes that SP is still regarded within some sports, and by some individuals, as an irrelevance, and the so-called 'macho' culture of sport may exaggerate such perceptions.

SOCIAL FACILITATION

Triplett's research

As we noted earlier, Triplett (1898) carried out what's widely considered to be the first social psychology experiment. But it seems to be at least as relevant to SP.

Cycling had increased enormously in popularity in the last decade of the nineteenth century, both as a pastime and a sport. Triplett's interest was stimulated by the common observation that racing cyclists go faster when racing or being paced than when riding alone (Hogg & Vaughan, 1998).

Competition can increase speed regardless of the kind of bicycle being ridden

ASK YOURSELF...
- Why do you think this effect might occur?

Triplett identified various possible explanations for this superior performance:

- the pacer in front produces a suction to pull the rider behind along, helping to conserve energy and providing shelter from the wind
- a 'brain-worry' theory, popular at the time, predicted that solitary cyclists did poorly because they worried about whether they were going fast enough. This exhausted their brain muscles!
- friends usually rode as pacers and probably encouraged the cyclists to keep up their spirits
- in a race, a follower might be hypnotised by the wheels in front, thus riding automatically and leaving more energy for a later, controlled burst
- a *dynamogenic theory* (favoured by Triplett) proposed that racing another person aroused a 'competitive instinct', which released 'nervous energy' (similar to arousal). The sight of movement in another rider suggested a higher speed and inspired greater effort. The energy of a movement was proportional to the idea of that movement. (It was believed at the time that to perform an action or movement, there first had to be an 'idea' of that action/movement; the idea 'suggested' the action/movement to be performed).

KEY STUDY 31.1 Is this a wind-up or a social psychology experiment? (Triplett, 1898)
- In his most famous experiment, 40 boys and girls aged 8 to 17 were tested under two conditions: working alone and working in pairs, each child competing against the other member of the pair.
- The apparatus consisted of two fishing reels, which turned silk bands around a drum (a 'competition machine'). Each reel was connected by a loop of cord to a pulley two metres away, and a small flag was attached to each cord. To complete one trial, a flag sewn to the silk band had to travel four times around the wheel.
- Some of the children were slower when competing against another child, most were faster, and others little affected.
- The faster children showed the effects of both 'the arousal of their competitive instincts and the idea of a faster movement'. The slower ones were overstimulated or 'going to pieces'.

In expanding on the dynamogenic theory, Triplett emphasised the ideo-motor responses; that is, the effects of one child's bodily movements acting as a cue for another child. These are essentially *non-social*. According to Hogg & Vaughan (1998), 'What is clear is that Triplett himself cannot be considered a social psychologist'. So, while Triplett's experiment is often cited as a (very early) study of social facilitation, it's not strictly a social psychological study at all.

Allport's research

According to Floyd Allport (1924), Triplett's narrow view of the role of competition could be broadened to include a more general principle: an improvement in performance can be produced by the mere presence of *conspecifics* (members of the same species). This is a form of influence he called *social facilitation*.

Allport instructed his participants not to try to compete against one another (and also prevented any collaboration) while engaging on a variety of tasks. These included crossing out all the vowels in a newspaper article, multiplication, and finding logical flaws in arguments. He found they performed better when they could see others working than when they worked alone, and he called this form of social facilitation the *co-action effect*.

Social facilitation also occurs when someone performs a task in front of an audience, that is, other people who aren't doing what s/he is doing. This is the *audience effect*. Other studies have shown that social facilitation can occur by simply telling participants that others are performing the same task elsewhere (Dashiell, 1935).

For the sportsperson, the fact that the presence of others may improve or impair performance is of considerable interest. Although most of the research has taken place in non-sports settings, it still has a direct bearing on sports situations (Woods, 1998).

ASK YOURSELF...

- In your own experience, do you 'perform' better when there are other people around?
- Does it matter that they're engaged in the same task as you?
- Might an 'audience' inhibit you?
- How is all of this affected by the particular task you're engaged in?

Explaining social facilitation

Zajonc's drive theory

The considerable research interest in social facilitation (much of it involving a range of species and a range of behaviours, from eating to copulation) died down at the end of the 1930s. But it was revived by Zajonc's (1965) *drive theory,* according to which social facilitation depends on the nature of the task, in particular, how simple and well learned it is. According to Zajonc:

> ... an audience impairs the acquisition of new responses and facilitates the emission of well-learned responses.

In other words, things a person already knows how to do (such as cancelling numbers and letters, and simple multiplication) are done *better* when others are present, but things which are complex or which participants are required to learn are done *less well* when others are present. These findings have been confirmed by others. But why?

Because people are relatively unpredictable, there's a clear advantage to the species for their presence to induce in us a state of alertness or readiness. So, an instinctive response to the presence of others (in whatever capacity) is an increase in drive level (or level of arousal). This, in turn, energises (causes us to enact) our *dominant responses,* that is, our best learned or habitual responses in that situation. On subjectively simple tasks (those considered to be simple by the performer), those dominant responses are likely to be correct. Hence, the presence of others will facilitate performance on simple tasks (*task enhancement).*

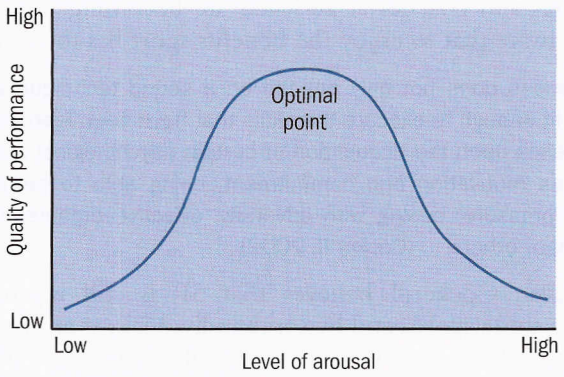


Figure 31.1 Graph showing the inverted U relationship between arousal and performance

However, when the task is complex, the effect of increased arousal is to make it more likely that incorrect or irrelevant responses will be performed and, hence, more errors are made (*task impairment*). The arousal produced by the presence of others, together with that produced by the task itself, produce a level beyond the optimum for ideal performance.

An evaluation of Zajonc's drive theory

Some critics have argued that even on well-learned tasks, a skilled athlete may perform poorly in front of others. This can be better explained by the *inverted U theory* (based on the Yerkes–Dodson law (see Figure 31.1) Oxendine (1970) found an inverted U relationship in several sports, but the amount of arousal necessary for optimal performance depended on the *nature of the skill* involved.

More complex skills (putting in golf) need a lower level of arousal, because arousal interferes with fine muscle movement and coordination, and cognitive activities such as concentration. But high arousal is useful in less complex skills that require strength, endurance, and speed (like tackling in football).

Many skills involve both strength and complexity, which are difficult to separate out (Jones & Hardy, 1990). For example, preparing to putt requires low muscle activity in the forearms, but high cognitive activity, while performing a maximum bench press in gym requires high muscle activity in the forearms and lower cognitive activity.

Open and closed skills

According to Woods (1998), arousal can be more detrimental to performance of open than closed skills.

- *Open skills* are performed in an unpredictable environment, so they make more cognitive demands on the

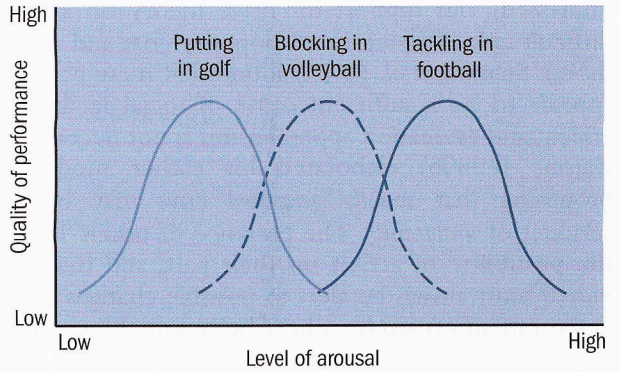

Figure 31.2 Graph showing the relationship between level of arousal and level of performance in three skills

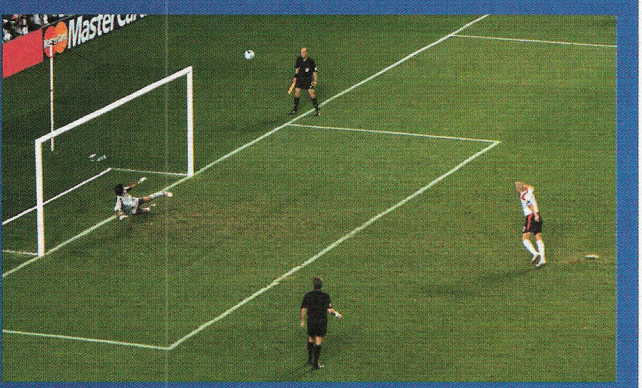
performer. The environment is constantly changing and players don't know what will happen; they have to make rapid decisions about what to do and when to do it.

ASK YOURSELF...
- Give an example of an open skill.

An example is that of a basketball player who has to be able to control the ball while noting the movement of team-mates and opposing players, as well as making tactical decisions. Dribbling a basketball is best learned by practising under a variety of conditions, so that it can be performed effectively whatever the circumstances.

◎ *Closed skills* are performed in a constant, predictable environment, so the performer knows in advance what to do and when to do it. Learning involves refining the skill until it's as perfect as possible, and then repeating it until it can be performed automatically (it becomes *habitual*).

ASK YOURSELF...
- Give an example of a closed skill.



A gymnast starting a routine is performing a closed skill, which is self-paced. But closed skills may also occur in an 'open' situation. For example, a netball player taking a penalty shot is performing a closed skill, but she must take account of environmental factors, such as the position of other players and likely rebounds. So, the penalty shot cannot be purely habitual and has some characteristics of an open skill (Woods, 1998).

Level of expertise

To perform well, someone just learning a sport should experience only very low levels of arousal. But the experienced performer will need much higher levels in order to achieve optimum performance. Because the learner's skills aren't yet automatic, s/he uses cognitive abilities to direct, monitor and control them. Any additional arousal may interfere with concentration, reducing the ability to control the skill successfully.

Box 31.3 The 'yips'

- This refers to the sudden, catastrophic breakdown in skilled performance. This rather strange phenomenon is characterised by an inability to perform a well-learned, well-practised skill ('choking' under pressure: Baumeister, 1984). It seems to strike suddenly from nowhere to debilitate an athlete severely – for months, years or even a whole career.
- In golf, it's been described as 'jerks, tremors or spasms' affecting the lower arm (Smith *et al.*, 2000). Similar phenomena seem to occur in other sports where precision and fine motor control are at a premium, such as cricket (especially bowling), tennis, snooker and darts. Eric Bristow is a prime example. At the height of his darts career, he found one day that he was unable to release the dart from his fingers. It took him ten years to recover.
- The yips has been explained by the *'catastrophe' model of performance in sport* (Fazey & Hardy, 1988). This predicts that there may be a sudden 'catastrophic' breakdown in performance (resulting from interactions between cognitive anxiety and physiological arousal), from which the athlete may find it difficult to recover.
- But the problem may have a neuromuscular, as well as psychological, origin. For example, 'focal dystonia' describes a similar condition among musicians and typists, originating from prolonged repetitive movements and abnormal pressure ('repetitive strain injury'). Over the course of a sporting career, it's certainly possible that an athlete will have performed similar repetitive movements *thousands*, even *hundreds of thousands*, of times (Graydon, 2002).

David Beckham's famous penalty shoot-out miss against Portugal in Euro 2004

- According to Baumeister (1984), the pressure to perform can make performers self-conscious, directing their conscious attention to the control of a motor skill

that is usually performed 'unconsciously' (automatically). Under pressure, the skilled performer (for whom the skill 'just happens') reverts to the level of a novice (who needs to 'talk his/her way through it'). This destroys the skill's *fluidity*: 'Intriguingly, perhaps you have to be an expert before a catastrophe can occur' (Graydon, 2002)

Personality

Performers with *low impulsivity* (low *extroversion/E* and low *neuroticism/N:* see Chapter 42) tend to be more highly aroused during the early part of the day. By contrast, those high on impulsivity are more highly aroused later in the day. This has implications for performance. For example, athletes rated high on impulsivity will need to use more relaxation and stress-reduction strategies when running in an evening compared with a morning race (Woods, 1998).

Cottrell's evaluation apprehension model (EAM)

Cottrell *et al.* (1968) found no social facilitation effect on three well-learned tasks when the two-person audience was inattentive (blindfolded) or merely present (only incidentally present, while supposedly waiting to participate in a different experiment). However, a non-blindfolded audience that carefully attended to the participant's performance, and had expressed an interest in watching, did produce a social facilitation (audience) effect.

According to Cottrell's (1968) *evaluation apprehension model* (EAM), it's *not* the presence of other people that increases arousal (as Zajonc's drive theory claims), but *apprehension* about being evaluated by them. We quickly learn that the social rewards and punishments (such as approval and disapproval) are dependent on others' evaluations of us, so the presence of others triggers an *acquired arousal drive* based on evaluation apprehension.

An evaluation of Cottrell's model

- If we're confident about our ability, then the awareness of being watched makes us perform well, but if we're not confident, then we're constantly worrying about how others are evaluating us.
- Cottrell *et al.* also showed that the more expert the audience, the more performance was impaired (the greater the evaluation apprehension).

ASK YOURSELF...

- Have you had personal experience of this (not necessarily in an athletic context)? (Consult the answers you gave to the previous *Ask Yourself* box – page 531.)

- Markus (1978) found support for Cottrell on an easy task (dressing in one's own clothes, having first undressed), but support for drive theory on a more difficult task (dressing in a laboratory coat and special shoes). Schmitt *et al.* (1986) found that mere presence appears to be a sufficient cause of social facilitation effects, and evaluation apprehension is not necessary.
- Zajonc (1980b) elaborated his earlier model by proposing that *socially generated drive* may be the product of *uncertainty.* The presence of others implies the possibility of action on their part, and the individual must always be alert to possible changes in the environment caused by others' behaviour. Uncertainty may be caused by the inability to anticipate how they'll act (Geen, 1995).

Baron's distraction–conflict theory (DCT)

The amount of information we can attend to at the same time is limited (see Chapter 13). Little attention is needed to perform an easy task, but more is needed for a complex one. According to Baron's (1986) *distraction–conflict theory* (DCT), while distraction alone can impair task performance, attentional conflict can also induce a drive that facilitates dominant responses. Together, these processes improve performance of easy tasks, but impair performance of difficult ones. The presence of other people makes demands on our attention, which can either impair or enhance performance, depending on the nature of the task.

Attention overload causes people to narrow their attention and focus on a small number of central cues. Complex tasks require attention to a large number of cues, so attention narrowing is likely to impair performance. On simple tasks (which involve few central cues), attention narrowing eliminates distraction and is likely to improve performance. This corresponds to Manstead & Semin's (1980) distinction between *controlled* and *automatic task performance* (see Box 31.3).

An evaluation of distraction–conflict theory

- Sanders *et al.* (1978) had participants perform easy and difficult tasks, either alone or co-acting with someone performing either the same or a different task. The reasoning is that someone performing a *different* task wouldn't be a relevant source of social comparison, and so distraction should be minimal. But another person performing the *same* task would be highly distracting. As predicted, participants in the same-task (*distraction*) condition made more mistakes on the difficult task and did better on the simple task, compared with the other conditions.
- Research shows that *any* form of stimulation (such as noise, movement, flashing lights) – not only the presence of other people – can produce the same facilitation or distraction effects (Hogg & Vaughan, 1998). An implication of this theory is that one way of preventing 'overload' is to cut out awareness of others and focus on the task in hand (Woods, 1998).

Non-drive explanations

The theories discussed above differ as to whether the drive is considered to be an innate response to the mere presence of other people, or a learned response based on evaluation apprehension or the product of attentional conflict. Although these are the best established and most extensively researched explanations, they aren't the only ones.

According to *self-awareness theory* (Carver & Scheier, 1981; Duval & Wicklund, 1972; Wicklund, 1975), we compare our actual selves (actual task performance) and ideal selves (how we'd like to perform: see Chapters 33 and 42). The discrepancy between them motivates us to close the gap. So, on easy tasks there's improved performance, but on difficult tasks the discrepancy may be too great and people give up trying, resulting in poorer performance. Self-awareness can be produced by co-actors, audience, or simply looking in a mirror.

An evaluation of explanations of social facilitation

- There are many different accounts of what might originally have seemed a rather basic, straightforward social phenomenon. Some have fared better than others, and many questions remain unanswered.
- Nevertheless, the study of audience effects remains an important topic for social psychology (Hogg & Vaughan, 1998).
- However, in a meta-analysis of social facilitation experiments involving over 24,000 participants, Bond & Titus (1983) concluded that the mere presence of other people accounted for no more than 0.3–3.0 per cent of the variation in performance.

Social facilitation in a sports setting

Most of the research described above has involved passive, and unbiased, audiences. But in a sports context, the 'audience' is usually far from unbiased. Rather, it's composed of active, often passionate, supporters.

Patriotic British tennis fans at Wimbledon

While research involving 'real' audiences is rare, one relevant area of research has looked at 'home advantage'.

Box 31.4 Does playing 'at home' improve or impair performance?

- For the major sports in the USA, teams win more home than away matches. This is true even when the visitors' 'away disadvantage' (such as the effects of travel and lack of familiarity with the ground) has been taken into account.
- Home advantage may be more important in the early rounds of a competition.
- When defending champions play at home, there's more chance of the home team cracking under the pressure.
- Home advantage is greater in sports such as basketball, where supporters are closer to the players. It's the intimacy with the crowd – not its size – which has most effect.

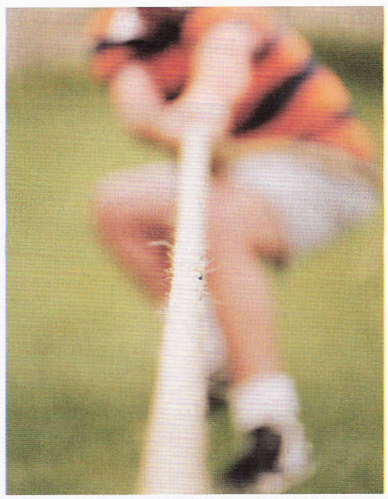
(Based on Woods, 1998)

ASK YOURSELF...

- If you support a football or rugby team, for example, check their results for last season. Did they perform better at home or away? (The chances are that unless they either won the championship or got relegated – in which case they probably performed consistently well or badly home and away – they did better at home.)
- How might the theories of social facilitation discussed above account for the various findings reported in Box 31.4?

Using social facilitation in coaching

According to Woods (1998):



- athletes who train alongside others are likely to put more effort into routine tasks, such as warm-ups
- when learning a new skill, it's preferable to keep observers away
- athletes should be encouraged to learn techniques that minimise the effect of distractors (other people, noise, heat, and so on); some techniques that help in the management of arousal include relaxation, imagery and self-talk.

INFLUENCES ON GROUP PERFORMANCE

Social inhibition

The Ringelmann effect

Can the presence of others have an *inhibiting* effect on performance, as well as a facilitating effect? Several years after Triplett's experiments, Ringelmann, a French professor of engineering, reported a series of studies in which the presence of others seemed to produce a loss

How hard he pulls depends on how many others are pulling

in motivation. (The studies had actually been conducted prior to Triplett's research, so strictly speaking these are the very first experiments in social psychology: Geen, 1995; Smith, 1995.) Ringelmann found that the more members there were in a tug-of-war team, the less hard each member pulled; that is, as the size of the group increased, so the amount of force exerted per person decreased (the *Ringelmann effect*). He explained this largely in terms of a loss of physical coordination, but he conceded that loss of motivation could also be involved.

Social loafing

Latané *et al.* (1979) revived the Ringelmann effect under the name of *social loafing*. Early demonstrations involved simple physical acts, such as shouting and hand-clapping, individually or in groups, with the general result that the intensity of output per person declined as additional members were added. For example, when participants were asked to cheer and clap as loudly as possible, the amount of noise produced per person (compared with individual performance) dropped by 29 per cent in a pair, 49 per cent in a four-person group, and 60 per cent in a six-person group.

Social loafing can be defined as the tendency for individuals to work less hard (to loaf) on a task when they believe that others are also working on the task, and that one's own effort will be pooled with that of the other group members, compared with either working alone or co-actively (where others are doing the same task but independently of each other). According to Geen (1995), the data are consistent with one of the major claims of *social impact theory* (Latané & Nida, 1980). This states that when a person is a member of a group subjected to social forces, the impact of those forces on each person in the group is diminished in inverse proportion to the number of people in the group – the larger the group, the smaller the impact.

Later studies have shown the effect to be very reliable and general, occurring in both physical and cognitive tasks, in laboratory and naturalistic settings, in both genders and in several cultures. However, a review by Karau & Williams (1995) concluded that gender and culture appear to moderate people's tendency to loaf. Although men and women in different cultures are susceptible to loafing, the effect is smaller for women than men, and for people living in Eastern cultures. Both women and people living in Eastern cultures tend to be more group- or collectively oriented in their thinking and behaviour (see Chapters 35 and 47).

Explanations of social loafing

Geen (1995) identifies four main explanations: *'free-riding', equalisation of perceived output, evaluation apprehension,* and *matching to standard.*

- *Free-riding* (Kerr, 1983) occurs when each member of a group perceives that there's a high probability that some other group members will solve the problem at hand, and that the benefits from this person's performance will go to all members. Each individual concludes that his/her contribution is dispensable, and so puts little effort into the group task. As a result, the importance of individual effort decreases as the size of the group increases.
- Related to this is the equalisation of perceived output (or the *sucker effect*): if people expect their fellow group members to become free-riders ('goof off'), they may respond by loafing in an effort to bring equality to an inequitable situation ('Why should I make more effort than the others?' or 'I'm no sucker'). This is sometimes called the *output equity hypothesis* (McIlveen, 1995). Men seem to dislike the sucker role more than women.
- *Evaluation apprehension,* as we saw earlier when discussing social facilitation, refers to anxiety about how others will judge us. If, as has been claimed, the tasks commonly used in social loafing studies are boring and meaningless, people will try to avoid doing them. If the efforts of group members are pooled, individuals can remain anonymous ('hide in the crowd', which is very similar to free-riding). It follows that making each person's contribution identifiable should eliminate social loafing.

  Williams *et al.* (1981) simply informed participants that their shouting responses would be identifiable to the experimenter, and, as predicted, they shouted as loudly in groups as when alone. This suggests that participants become apprehensive about being evaluated by the experimenter. This is especially likely when participants believe their performance is being *compared* with that of their co-actors performing the same task. They are, effectively, in competition. The higher the level of evaluation apprehension, the lower the level of social loafing (Harkins & Jackson, 1985).

- *Matching to standard* assumes that apprehension over the possibility of being evaluated by the experimenter causes the participant to match a standard for performance set by the experimenter (and that this matching is avoided under conditions that allow social loafing). According to Szymanski & Harkins (1987), the explicit statement of a standard relevant to the activity is sufficient to reduce social loafing.

Implications of social loafing for sports coaches

ASK YOURSELF...
- Based on the social loafing research discussed above, what advice would you give sports coaches?

According to Woods (1998), social loafing is essentially the result of a decrease in motivation. While 'There's no 'I' in 'team'' is a well-worn sporting cliché, she believes that research on social loafing shows that coaches ignore the 'I' at their peril. For Woods:

> Group goals are achieved by individuals, so it is important to identify individual behaviours which help group performance and try to encourage those behaviours. Monitoring and feedback on performance (to both individuals and the group) are better than feedback only on group performance ...

Group cohesion

ASK YOURSELF...
- How would you define a 'team'?
- Is it more than just the sum of the individual members (as with any group)?
- Apart from their skill levels, how do teams differ from each other?

According to Hogg & Vaughan (1998), *group cohesion* (or *cohesiveness*) is one of the most basic properties of a group, and is otherwise known as solidarity, *esprit de corps,* team spirit, or morale. For Hogg and Vaughan, a cohesive group or team is:

> ... the way it 'hangs together' as a tightly knit, self-contained entity characterised by uniformity of conduct and mutual support among members ...

Cohesion can vary between groups, contexts, and across time. Groups with extremely low levels of cohesion hardly appear to be groups at all, and so the term may capture the very essence of being a group: the psychological process that transforms a collection of individuals into a group.

Festinger (1950) defined cohesiveness as a field of forces acting on the individual deriving from the attraction of the group and its members, and the degree to which the group satisfies individual goals. Cohesiveness is responsible for the continuity of group membership and adherence to group norms/standards.

Tottenham Hotspur's triumphant Worthington Cup winning team, 1999

According to Hogg (1992), most research defines cohesiveness in terms of attraction to the group and interpersonal attraction. Factors which increase interpersonal attraction (such as similarity, cooperation, interpersonal acceptance and shared threat: see Chapter 28) generally increase cohesiveness. This, in turn, causes, or is associated with, conformity to group norms, accentuated similarity, improved ingroup communication, and increased liking.

Personal vs social attraction

Hogg (1992, 1993) proposed a distinction between *personal attraction* (true interpersonal attraction based on close relationships) and *social attraction* (inter-individual liking based on common group membership). As Hogg & Vaughan (1998) say:

> Personal attraction is nothing to do with groups, while social attraction is the 'liking' component of group membership ...

ASK YOURSELF...
- How might social attraction be understood in terms of *self-identity theory* (SIT: see Chapter 25)?
- In what other ways might SIT be relevant to understanding group cohesiveness?

Attraction is one of a large number of effects produced by *self-categorisation,* as specified in self-identity theory (SIT). One advantage of this distinction between personal and social attraction is that group cohesiveness isn't reduced to interpersonal attraction, and it also applies equally to small interactive groups and to large-scale social categories (such as 'ethnic group' and 'nation').

Hogg & Hardie (1991) gave questionnaires to a football team in Australia. Perceptions of team *prototypicality* (the typical/ideal defining features of team members) and norms were significantly related to measures of group-

based social attraction, but *not* to measures of interpersonal attraction. This differential effect was strongest among members who themselves identified most strongly with the team. Similar findings were obtained with netball teams (Hogg & Hains, 1996).

Task vs social cohesion

Athletes often report that team cohesion is a source of satisfaction in their lives. Yet there is conflicting evidence as to whether the most cohesive teams are always the most successful. This is related to whether teams have been analysed in terms of:

- *task cohesion* – the degree to which group members work together and are committed to achieve common goals, such as winning a match, or
- *social cohesion* – the degree to which group members like each other and get on well, trust, and support each other.

These two aspects/dimensions are independent of each other. You might be very committed to achieving your team's goals, but not be particularly attached to the other team members. A team in which members get on well and are very committed to achieving common goals is at the *performing* stage of group development (Tuckman, 1965). This team may be successful. But equally, a team in which there are major disputes (and which is at the *storming* stage: Tuckman, 1965) could do well if there's a high degree of commitment to the common goal (Woods, 1998).

Factors associated with group cohesion

Type of sport

In *interactive* sports, such as football, the cohesive team (where members rely on each other to perform successfully) tends to be more successful. But in *co-active* sports, such as swimming (in which individual performance doesn't depend on others' performance), degree of cohesion seems to have little effect.

ASK YOURSELF...

- Can you relate this finding to Aronson's *jigsaw method* used to reduce racial prejudice and discrimination (see Chapter 25)?
- Analyse other sports in terms of the interactive/co-active distinction. Do some sports combine elements of both?
- Can a similar distinction be made with respect to *opponents?*

Box 31.5 Other factors associated with group cohesion

- **Group size:** The smaller the group, the greater the cohesion. This may be because there's more opportunity for members to interact, and less chance that faulty group processes will occur.
- **Similarity:** The more similar the members (in terms of status and characteristics, such as age and skill level), the greater the cohesion.
- **Success:** The more successful the team, the greater the cohesion.
- **External threats:** These may increase group cohesion by forcing members to ignore internal divisions and conflicts.

(Based on Woods, 1998)

ASK YOURSELF...

- Can you relate external threats to *common/superordinate goals,* as discussed in Chapter 25?

Factors affecting group performance

A good team is more than a group of skilled players. Members need to work together effectively in order to be successful. According to Steiner (1972), this can be expressed as:

Actual productivity = Potential productivity – Losses due to faulty group processes

In other words, to improve team performance, coaches need to increase the skills and performance of individuals (potential productivity), while reducing faulty group processes. The latter include coping with *excess arousal* and dealing with *social loafing* (both discussed above), *competitiveness,* and *poor coordination.*

Competition and cooperation

Although competitiveness is an essential part of sporting activity, cooperation is also essential, especially in team sports. In a review of the research, Johnson & Johnson (1985) concluded that cooperation produced higher standards in many more situations than competitiveness (including individual situations). But most of these studies weren't conducted in sports settings, in which competitiveness can produce exceptional effort, as well as damaging consequences. The latter may be most evident with younger or novice players, whose experience of failure in a highly competitive setting may even cause them to quit the sport. Increasingly, coaches are trying to strike a balance between these twin aspects of sport (Woods, 1998).

Coordination factors

These refer to the degree to which each player's skills are meshed together as tightly as possible, and are a central feature of interactive sports (such as football, rugby, and

volleyball). Training time should include practice in passing, timing, and the pattern of players' movements. For example, coordination between the three players involved in taking a penalty corner in hockey is crucial:

> One notices time and time again that technically superior teams ... (can be beaten because of) ... lack of concentration, careless positioning and too much improvisation in execution ... the penalty corner is grossly neglected in training, especially by club teams ... (Wein, 1985, in Woods, 1998)

Co-active sports (such as swimming and golf), where individual performance doesn't depend on others, suffer much less from coordination factors (Woods, 1998).

CHAPTER SUMMARY

- **Sport psychology** (SP) is the scientific study of human behaviour and experience in sport. This includes recreational activities and exercise, as well as competitive sport.
- While their roles overlap, it's possible to distinguish **clinical**, **research** and **education sport psychologists**. Many of the issues they address draw on areas of research in mainstream and applied psychology, such as **treatment of mental disorders**, **stress management**, **skill learning** and the role of **personality factors**.
- Zuckerman's **sensation-seeking scale** has successfully predicted attraction to sporting activities that involve high levels of risk and thrill.
- **Extreme athletes** have been described as **T types**, who may have fewer dopamine receptors in their brains. But adrenaline surges have also been recorded during more mental activities, such as chess.
- Triplett proposed a number of **non-social explanations** for why racing cyclists go faster when racing or being paced, compared with riding alone.
- Allport coined the term **social facilitation** to refer to improved performance caused by the mere presence of **conspecifics**. Two forms of social facilitation are the **co-action** and **audience effects**.
- Several explanations of social facilitation have been proposed, including Zajonc's **drive theory**, Cottrell's **evaluation apprehension model** (EAM), Baron's **distraction–conflict theory** (DCT), and **self-awareness theory**.
- There's evidence for an **inverted U relationship** between performance and arousal. This depends on the **nature of the skill** involved (such as **open/closed**), **level of expertise** and **personality**.
- The '**Ringelmann effect**' describes one way in which the presence of others can **inhibit** performance. This idea was later revived and renamed **social loafing**.
- Major explanations of social loafing include '**free-riding**', the **equalisation of perceived output/sucker effect**, **evaluation apprehension**, and **matching to standard**.
- **Group cohesion/cohesiveness** is a basic property of a group. Most research defines cohesiveness in terms of attraction, but fails to distinguish between **personal** and **social attraction**. Only social attraction is relevant to group membership as such.
- Factors affecting group cohesion include the **type of sport** (interactive or co-active), **stability**, **group size**, **similarity** and **external threats.**
- Factors affecting **group performance** include **arousal**, **social loafing**, **competitiveness**, **cooperation** and **coordination**.

Links with other topics/chapters

- Exercise is widely accepted as a means of *stress reduction,* and also has several other benefits for both *physical and mental health* (Chapter 12).
- One study of T types has found that people with certain *addictive and impulsive personality traits* have fewer dopamine receptors to record sensations of pleasure and satisfaction. This drives them to overindulge in *substances or activities* that stimulate their existing receptors (Chapters 8 and 46).
- Triplett's experiment is considered by many to be the first study of *social motivation* (Chapter 9).
- Zajonc's explanation of social facilitation is based on *Hull's learning theory* (Chapter 9).
- The Yerkes–Dodson law (1908) is concerned with the general relationship between *arousal and performance* (Chapter 7) and has been applied to the relationship between fear arousal and *attitude change* (Chapter 24).
- Evaluation apprehension is a form of *social anxiety* (Chapter 44).
- Baumeister's explanation of the yips is related to theories of *divided attention,* such as Schneider and Shiffrin's *automaticity model* (Chapter 13).
- The free-riding explanation of social loafing is similar to the *diffusion of responsibility* explanation of *bystander intervention* (Chapter 30).
- In group-oriented (*collectivist*) cultures, such as China and Japan, making the tasks more realistic and relevant to everyday life not only eliminates social loafing but reverses it. The presence of others enhances performance on the same tasks which, in more *individualist,* western cultures produce social loafing (Smith & Bond, 1993) (Chapter 47).
- Other effects produced by self-categorisation, as specified by SIT, include *stereotyping* (Chapter 22), *intergroup differentiation, ethnocentrism* and *ingroup solidarity* (Chapter 25), and *conformity* (Chapter 26).

EARLY EXPERIENCE AND SOCIAL DEVELOPMENT

INTRODUCTION AND OVERVIEW

The study of attachments and their loss or disruption represents an important way of trying to understand how early experience can affect later development. Although it was a central tenet of Freud's psychoanalytic theory that experience during the first five years of life largely determines the kind of adults we become, it's really only since the 1950s that developmental psychologists have systematically studied the nature and importance of the child's tie to its mother.

This began with the English psychiatrist John Bowlby. He was commissioned by the World Health Organization (WHO) to investigate the effects on children's development of being raised in institutions (in the aftermath of the Second World War: the photograph on the previous page shows wartime evacuees). The central concept discussed in his report (*Maternal Care and Mental Health*, 1951) was *maternal deprivation*, which has become almost synonymous with the harmful effects of not growing up within a family.

However, Bowlby has been criticised for exaggerating the importance of the mother–child relationship. There's much more to attachment than attachment to the mother. Fathers are attachment figures in their own right, as are siblings. Children's social development involves the expansion of the network of relationships to include teachers, neighbours and classmates, some of whom will become their friends.

There's now a considerable body of research into attachments beyond infancy and childhood, especially between adult sexual partners, and many psychologists have questioned the deterministic nature of the early years.

According to Schaffer (2004), whether the nature of our earliest relationships exerts as profound an influence on all subsequent close relationships as Freud suggested remains a contentious issue. But there's no question that relationship formation remains a lifelong issue, and that:

> ... relationships provide the context in which all of a child's psychological functions develop ... What is also certain is that differences among children in the nature of their relationships with others can have profound implications for the particular developmental path that each child embarks upon. Understanding relationship formation is thus an essential part of understanding child development ... (Schaffer, 2004)

THE DEVELOPMENT AND VARIETY OF ATTACHMENTS

What is sociability?

Sociability refers to one of three dimensions of temperament (the others being *emotionality* and *activity*), which are taken to be present at birth and inherited (Buss & Plomin, 1984). Specifically, sociability is:

- seeking and being especially satisfied by rewards from social interaction
- preferring to be with others
- sharing activities with others
- being responsive to and seeking responsiveness from others.

While babies differ in their degree of sociability, it's a general human tendency to want and seek the company of others. As such, sociability can be regarded as a prerequisite for attachment development: the attraction to *people in general* is necessary for attraction to *particular individuals* (attachment figures). It corresponds to the *pre-attachment* and *indiscriminate attachment phases* of the attachment process (see below).

What is attachment?

According to Kagan *et al.* (1978), an attachment is:

> ... an intense emotional relationship that is specific to two people, that endures over time, and in which prolonged separation from the partner is accompanied by stress and sorrow.

While this definition applies to attachment formation at any point in the life cycle, our first attachment acts as a *prototype* (or model) for all later relationships. Similarly, although the definition applies to any attachment, the crucial first attachment is usually taken to be with the mother.

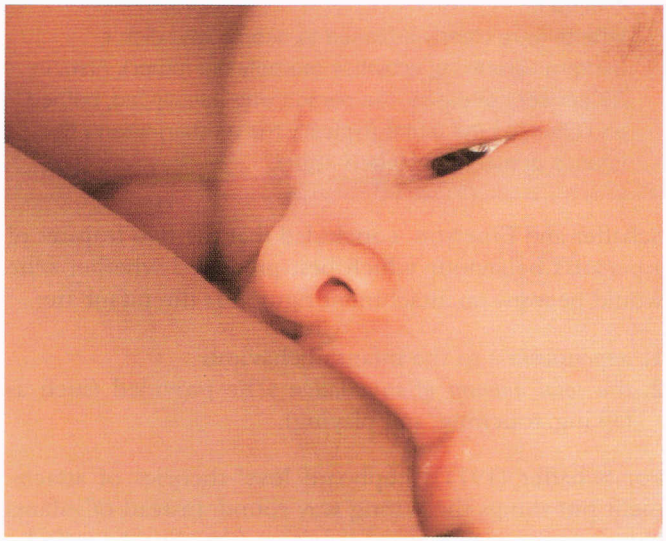
Phases in the development of attachments

The attachment process can be divided into several phases (Schaffer, 1996a).

1. The *pre-attachment phase* lasts until about three months of age. From about six weeks, babies develop an attraction to other human beings in preference to physical aspects of the environment. This is shown through behaviours such as nestling, gurgling, and smiling, (the *social smile*) which are directed to just about anyone.
2. At about three months, infants begin to discriminate between familiar and unfamiliar people, smiling much more at the former (the social smile has now disappeared). However, they allow strangers to handle and look after them without becoming noticeably distressed, provided they're cared for adequately. This *indiscriminate attachment phase* lasts until around seven months.
3. From about seven or eight months, infants begin to develop specific attachments. This is demonstrated through actively trying to stay close to certain people (particularly the mother) and becoming distressed when separated from them (*separation anxiety*). This *discriminate attachment phase* occurs when an infant can consistently tell the difference between its mother and other people, and has developed *object permanence* (the awareness that things – in this case, the mother – continue to exist even when they cannot be seen: see Chapter 34).

Also at this time, infants avoid closeness with unfamiliar people and some, though not all, display the *fear-of-strangers response*. This includes crying and/or trying to move away, which are usually triggered only when a stranger tries to make direct contact with the baby (rather than when the stranger is just 'there').

4. In the *multiple attachment phase* (from about nine months onwards), strong additional ties are formed with other major caregivers (such as the father, grandparents, and siblings) and with non-caregivers (such as other children). Although the fear-of-strangers response typically weakens, the strongest attachment continues to be with the mother.



THEORIES OF THE ATTACHMENT PROCESS

'Cupboard love' theories

According to *psychoanalytic* accounts, the infant becomes attached to its caregiver (usually the mother) because of his/her ability to satisfy its instinctual needs. For Freud (1926):

> The reason why the infant in arms wants to perceive the presence of its mother is only because it already knows that she satisfies all its needs without delay.

Freud believed that healthy attachments are formed when feeding practices satisfy the infant's needs for food, security, and oral sexual gratification (see Chapter 42). Unhealthy attachments occur when infants are *deprived* of food and oral pleasure, or are *overindulged*. Thus, psychoanalytic accounts stress the importance of feeding, especially breast-feeding, and of the maternal figure.

Is this really all there is to attachment formation?

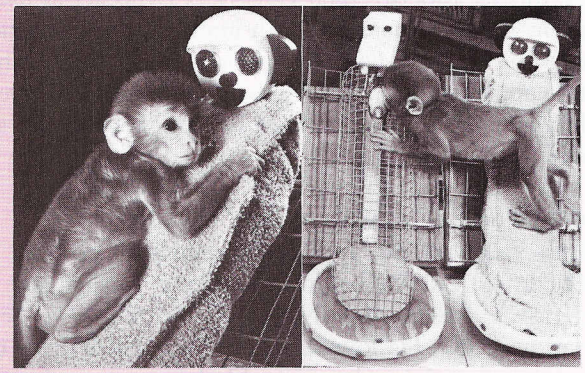
ASK YOURSELF...

- What do you think the *behaviourist* account of attachment might be? (See Chapter 11.)

The *behaviourist* view of attachment also sees infants as becoming attached to those who satisfy their physiological needs. Infants associate their caregivers (who act as *conditioned* or *secondary reinforcers*) with gratification/satisfaction (food being an *unconditioned* or *primary reinforcer*), and they learn to approach them to have their needs met. This eventually generalises into a feeling of security whenever the caregiver is present.

An evaluation of 'cupboard love' theories

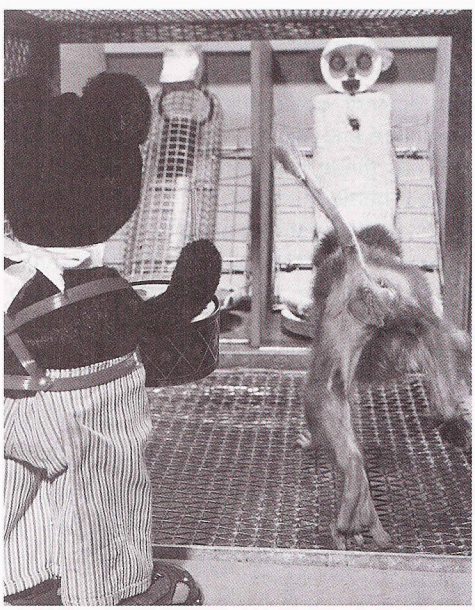
- Both behaviourist and psychoanalytic accounts of attachment as 'cupboard love' were challenged by Harlow's studies involving rhesus monkeys (e.g. Harlow, 1959; Harlow & Zimmerman, 1959). In the course of studying learning, Harlow separated newborn monkeys from their mothers and raised them in individual cages. Each cage contained a 'baby blanket', to which the monkey became intensely attached, showing great distress when it was removed for any reason. This apparent attachment to its blanket, and the display of behaviour comparable to that of an infant monkey actually separated from its mother, seemed to contradict the view that attachment comes from an association with nourishment.



KEY STUDY 32.1 A cuddle's worth more than food to a rhesus monkey (Harlow, 1959; Harlow & Zimmerman, 1959)

- To determine whether food or the close comfort of a blanket were more important, Harlow placed infant rhesus monkeys in cages with two 'surrogate (substitute) mothers'.
- In one experiment, one of the surrogate mothers was made from wire and had a baby bottle attached to 'her'. The other was made from soft and cuddly terry cloth, but didn't have a bottle attached.
- The infants spent most of their time clinging to the cloth mother, even though 'she' provided no nourishment. Harlow concluded from this that monkeys have an unlearned need for *contact comfort*, which is as basic as the need for food.

ASK YOURSELF...



- If the cloth mother had been fitted with a bottle but the wire mother hadn't, would the baby's preference for the cloth mother still have indicated an unlearned need for contact comfort?

By fitting only the wire mother with a bottle, Harlow was trying to separate the two variables (the need for food and the need for something soft and cuddly), so as to assess their relative importance. If the cloth mother had been fitted with a bottle, it would have been impossible to interpret the infants' clinging behaviour: was it due to the food or to her being soft and cuddly?

Rhesus monkey displaying contact comfort

The cloth surrogate also served as a 'secure base' from which the infant could explore its environment. When novel stimuli were placed in the cage, the infant would gradually move away from the 'mother' for initial exploration, often returning to 'her' before exploring further. When 'fear stimuli' (such as an oversized wooden insect or a toy bear loudly beating a drum) were placed in the cage, the infant would cling to the cloth mother for security before exploring the stimuli. But when it was alone or with the wire surrogate, it would either 'freeze' and cower in fear, or run aimlessly around the cage.

Infant monkeys frightened by a novel stimulus (in this case a toy teddy bear banging a drum) retreat to the terry cloth-covered 'mother' rather than to the wire 'mother'

◎ Later research showed that when the cloth 'mother' had other qualities, such as rocking, and providing warmth and food, the attachment was even stronger (Harlow & Suomi, 1970). This is similar to what happens when human infants have contact with parents who rock, cuddle, and feed them.

Although attachment clearly doesn't depend on feeding alone, the rhesus monkeys reared exclusively with their cloth 'mothers' failed to develop normally. They became extremely aggressive adults, rarely interacted with other monkeys, made inappropriate sexual responses, and were difficult (if not impossible) to breed. So, in monkeys at least, normal development seems to depend on factors other than having something soft and cuddly to provide comfort. Harlow and Suomi's research indicates that one of these is *interaction with other members of the species* during the first six months of life.

◎ Research on attachment in humans also casts doubt on 'cupboard love' theories.

KEY STUDY 32.2 Feeding isn't everything for Scottish infants (Schaffer & Emerson, 1964)

- Sixty infants were followed up at four-weekly intervals throughout their first year, and then again at 18 months.
- Mothers reported on their infants' behaviour in seven everyday situations involving separations, such as being left alone in a room, with a babysitter, and put to bed at night. For each situation, information was obtained regarding whether the infant protested or not, how much and how regularly it protested, and whose departure elicited it.
- Infants were clearly attached to people who didn't perform caretaking activities (notably the father). Also, in 39 per cent of cases, the person who usually fed, bathed and changed the infant (typically the mother) wasn't the infant's primary attachment figure.

Schaffer and Emerson concluded that the two features of a person's behaviour which best predicted whether s/he would become an attachment figure for the infant are:

1. *responsiveness* to the infant's behaviour
2. the *total amount of stimulation* s/he provided (such as talking, touching, and playing).

For Schaffer (1971), 'cupboard love' theories of attachment put things the wrong way round. Instead of infants being passive recipients of nutrition (they 'live to eat'), he prefers to see them as *active seekers of stimulation* (they 'eat to live').

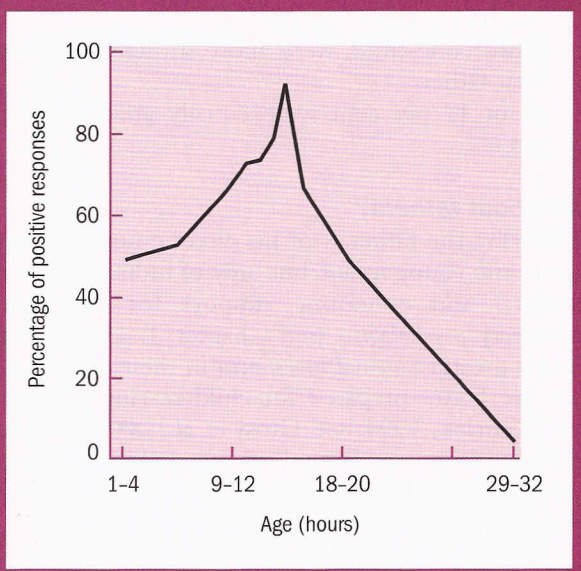
Ethological theories

The term 'attachment' was actually introduced to psychology by *ethologists*. Lorenz (1935) showed that some non-humans form strong bonds with the first moving objects they encounter (usually, but not always, the mother). In *precocial* species (in which the new-born is able to move around and possesses well-developed

sense organs), the mobile young animal needs to learn rapidly to recognise its caregivers and to stay close to them. Lorenz called this *imprinting*. Since imprinting occurs simply through perceiving the caregiver without any feeding taking place, it too makes a 'cupboard love' account of attachment seem less valid, at least in goslings.

Box 32.1 Some characteristics of imprinting

- The response of following a moving individual/object indicates that a bond has been formed between the infant and the individual/object on which it's been imprinted.
- Ethologists see imprinting as an example of a *fixed-action pattern* (FAP), which occurs in the presence of a species-specific releasing stimulus (or *sign stimulus*).
- Lorenz saw imprinting as unique, because (a) it occurs only during a brief *critical period* of life, and (b) once it has occurred, is *irreversible*. This is supported by the finding that when animals imprinted on members of other species reach sexual maturity, they may show a sexual preference for members of that species.



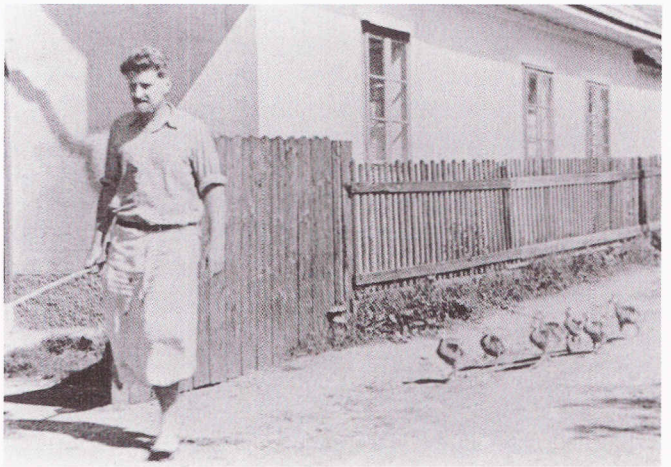


Figure 32.1 The graph represents the relationship between imprinting and the age (hours after hatching) at which a duckling was exposed to a moving model of a male duck

A *critical period* is a restricted time period during which certain events must take place if normal development is to occur (Bornstein, 1989). Lorenz saw imprinting as being genetically 'switched on', and then 'switched off' again at the end of the critical period. However, studies have shown that the critical period can be extended by changing the environment in certain ways. This has led some researchers (e.g. Sluckin, 1965) to propose instead the existence of a *sensitive period:* learning is *most likely* to happen at this time, and will occur most easily, but it may still occur at *other times.* Also, imprinting is reversible (at least in the laboratory: see Gross *et al.*, 2000).

Lorenz being followed by goslings which had imprinted on him soon after hatching

ASK YOURSELF...

- How relevant are Harlow's and Lorenz's findings with rhesus monkeys and goslings respectively to understanding human attachments?

Most psychologists would agree that the only way to be sure about a particular species is to study that species. To generalise the findings from rhesus monkeys and goslings to human infants is dangerous (although less so in the case of rhesus monkeys). However, Harlow's and Lorenz's findings can suggest how attachments might be formed in humans. Indeed, Bowlby was greatly influenced by ethological theory, especially by Lorenz's concept of imprinting.

Bowlby's theory

This represents the most comprehensive theory of human attachment formation. Bowlby (1969, 1973) argued that because new-born human infants are entirely helpless, they're *genetically programmed* to behave towards their mothers in ways that ensure their survival.

Box 32.2 Species-specific behaviours used by infants to shape and control their caregivers' behaviour

Sucking: While sucking is important for nourishment, not all sucking is nutritive. *Non-nutritive sucking*, also seen in non-humans, seems to be an innate tendency which inhibits a new-born's distress. In western societies, babies are often given 'dummies' (or 'pacifiers') to calm them when they're upset.

Cuddling: Human infants adjust their postures to mould themselves to the contours of the parent's body. The reflexive response that encourages front-to-front contact with the mother plays an important part in reinforcing the caregiver's behaviour (see Box 32.1).

Looking: When parents don't respond to an infant's eye contact, the infant usually shows signs of distress. An infant's looking behaviour, therefore, acts as an invitation to its mother to respond. If she fails to do so, the infant becomes upset and avoids further visual contact. By contrast, mutual gazing is rewarding for an infant.

Smiling: This seems to be an innate behaviour, since babies can produce smiles shortly after birth. Although the first 'social smile' doesn't usually occur before six weeks (see page 542), adults view the smiling infant as a 'real person', which they find very rewarding.

Crying: Young infants usually cry only when hungry, cold, or in pain, and crying is most effectively ended by picking up and cuddling them. Caregivers who respond quickly during the first three months tend to have babies that cry *less* during the last four months of their first year than infants with unresponsive caregivers (Bell & Ainsworth, 1972).

The mother also inherits a genetic blueprint which programmes her to respond to the baby. There's a critical period during which the *synchrony of action* between mother and infant produces an attachment. In Bowlby's (1951) view, mothering is useless for all children if delayed until after two-and-a-half to three years, and for most children if delayed until after 12 months.

Strictly speaking, it's only the child who's *attached* to the mother, while she is *bonded* to her baby. The child's attachment to its mother helps to regulate how far away from the mother the child will move, and the amount of fear it will show towards strangers. Generally, attachment behaviours (see Box 32.2) are more evident when the child is distressed, unwell, afraid, or in unfamiliar surroundings.

Bowlby believed that infants display a strong innate tendency to become attached to one particular adult female (not necessarily the natural mother), a tendency he called *monotropy*. This attachment to the mother-figure is *qualitatively* different (different in kind) from any later attachments. For Bowlby (1951):

> Mother love in infancy is as important for mental health as are vitamins and proteins for physical health.

ASK YOURSELF...

- Do you agree with Bowlby that the infant's relationship with its mother is unique, or are men just as capable as women of providing adequate parenting and becoming attachment figures for their young children?

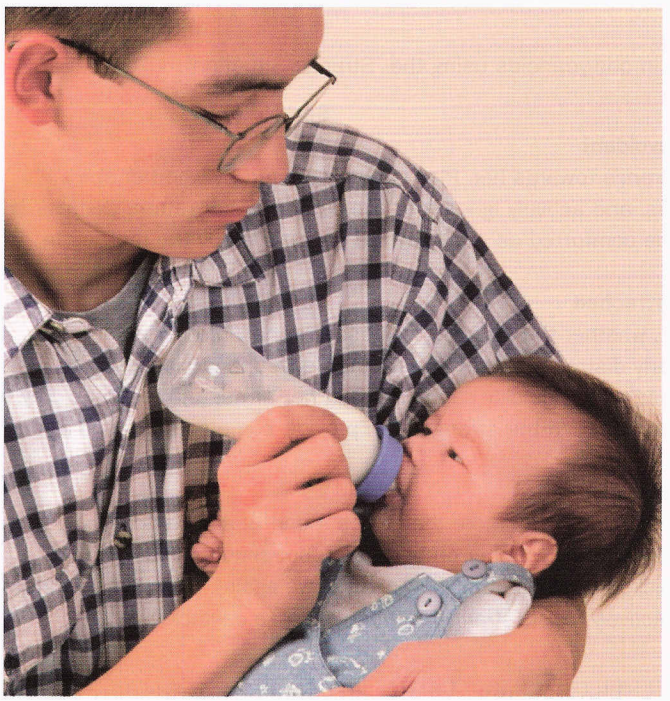
An evaluation of Bowlby's theory

- Bowlby's views on monotropy have been criticised. For example, infants and young children display a whole range of attachment behaviours towards a variety of attachment figures other than their mothers. In other words, the mother isn't special in the way the infant shows its attachment to her (Rutter, 1981).
- Although Bowlby didn't deny that children form multiple attachments, he saw attachment to the mother as being unique: it's the first to develop and is the strongest of all. However, Schaffer & Emerson's (1964) study (see Key Study 32.2) showed that multiple attachments seem to be the rule rather than the exception:
  - at about seven months, 29 per cent of infants had already formed several attachments simultaneously (10 per cent had formed five or more)
  - at 10 months, 59 per cent had developed more than one attachment
  - by 18 months, 87 per cent had done so (one-third had formed five or more).

  Although there was usually one particularly strong attachment, most infants showed multiple attachments of varying intensity:
  - only half of the 18-month-olds were most strongly attached to their mothers
  - almost one-third were most strongly attached to their fathers
  - about 17 per cent were equally attached to both parents.

What about fathers?

For Bowlby, the father is of no direct emotional significance to the young infant, but only of indirect value as an emotional and economic support for the mother. *Evolutionary psychologists* (see Chapter 2) see mothers as having a greater *parental investment* in their offspring, and hence are better prepared for child-rearing and attachment (Kenrick, 1994: see Gross *et al.*, 2000). However, Bowlby's views on fathers as attachment figures are disputed by findings such as those of Schaffer and Emerson.



CRITICAL DISCUSSION 32.1 How good are fathers at being mothers?

- Framing the question this way, of course, rests on the implicit assumption that women are 'natural' parents. This view of women is reflected in Bowlby's theory of monotropy and the complementary responsiveness of mothers to their babies (the 'maternal instinct').
- Based on this view of women-as-mothers, any departure from the traditional division of labour in child care has been greeted with suspicion: men inevitably will provide inferior parenting (Schaffer, 2004).
- Although *men as principal parents* is still a minority phenomenon, it's by no means as unusual as it used to be. Fathers' participation in child-rearing has certainly become much more common and an increasing number of children now live in father-headed families.

- There's considerable cultural variation in the extent of fathers' involvement in child care. This suggests that whatever sex differences exist in this respect are a matter of *social convention* and not an 'immutably fixed part of being male or female' (Schaffer, 2004) or *biology*.
- Although the evidence is sparse, there's no indication that the development of children brought up by a man differs in any way from that of others. Direct observation of men in their fathering role has shown them to be capable of as much warmth and sensitivity as women (Schaffer, 2004).
- According to Parke (1981):

  Both mother and father are important attachment objects for their infants, but the circumstances that lead to selecting mum or dad may differ.

Rather than being poor substitutes for mothers, fathers make their own unique contribution to the care and development of infants and young children (at least in two-parent families). Children's developmental outcome is affected not by the parents' gender, but by the kind of relationship that exists within each individual parent–child couple (Parke, 2002).

Does the baby really mind that the person who feeds it isn't female?

INDIVIDUAL AND CULTURAL VARIATIONS IN ATTACHMENT

A pioneering study of individual differences in children's attachment to their mothers was conducted by Ainsworth (1967) in Uganda.

CROSS-CULTURAL STUDY 32.1

Ainsworth's (1967) Uganda study

- Ainsworth studied 28 unweaned babies from several villages near Kampala, Uganda. At the beginning of the study, the babies ranged from 15 weeks to two years of age.
- They were observed every two weeks, for two hours at a time, over a nine-month period. Visits took place in the family living-room, where Ugandan women generally entertain in the afternoon. The mothers were interviewed (with the help of an interpreter), and naturalistic observations were made of the occurrence of specific attachment-related behaviours.
- Ainsworth was particularly interested in individual differences between mother–child pairs regarding the quality of their attachment relationships. To tap into these differences, she devised various rating scales. The most important of these in terms of her future research was a scale for evaluating maternal sensitivity to the baby's signals.
- Individual differences among babies were assessed by classifying them into three groups: securely attached, insecurely attached, and the not-yet-attached. These infant classifications were significantly correlated with ratings of the mothers' sensitivity (based purely on interview data) and the amount of holding by the mother (based on observation).

Ainsworth replicated her Ugandan study in Baltimore, USA (Ainsworth *et al.*, 1971, 1978). Van Ijzendoorn & Schuengel (1999) describe the Baltimore study as the most important study in the history of attachment research. Like the earlier study, both interviews and naturalistic observation were used, but the latter now played a much greater role.

Also like the Uganda study, the Baltimore study was *longitudinal:* 26 mother–infant pairs were visited at home every three to four weeks, each visit lasting three to four hours, for the first year of the baby's life. In order to make sense of the enormous amount of data collected for each pair (72 hours' worth), there needed to be an *external criterion measure* (some standard against which to compare the observations). The criterion chosen was the *Strange Situation* (see Figure 32.2, page 549, and Table 32.1 page 548).

The Strange Situation (SS) had been devised earlier by Ainsworth & Wittig (1969). They wanted to study how the baby's tendencies towards attachment and exploration interact under conditions of low and high stress. They believed that the balance between these two systems could be observed more easily in an unfamiliar environment. In the Baltimore study, the SS was modified to enable infant and maternal behaviour patterns to be classified.

Group data confirmed that babies explored the playroom and toys more vigorously in the mothers' presence

Table 32.1 The eight episodes of the 'Strange Situation'

Episode	Persons present	Duration	Brief description
1	Mother, baby, observer	30 seconds	Observer introduces mother and baby to experimental room, then leaves
2	Mother, baby	3 minutes	Mother is non-participant while baby explores; if necessary, play is stimulated after two minutes
3	Stranger, mother, baby	3 minutes	Stranger enters. First minute: stranger silent. Second minute: stranger converses with mother. Third minute: stranger approaches baby. After three minutes, mother leaves unobtrusively
4	Stranger, baby	3 minutes or less*	First separation episode. Stranger's behaviour is geared to the baby's
5	Mother, baby	3 minutes or more**	First reunion episode. Stranger leaves. Mother greets and/or comforts baby, then tries to settle baby again in play. Mother then leaves, saying 'bye-bye'
6	Baby	3 minutes or less*	Second separation episode
7	Stranger, baby	3 minutes or less*	Continuation of second separation. Stranger enters and gears her behaviour to baby's
8	Mother, baby	3 minutes	Second reunion episode. Mother enters, greets baby, then picks up baby. Meanwhile, stranger leaves unobtrusively

*Episode is ended early if baby is unduly distressed.

** Episode is prolonged if more time is required for baby to become reinvolved in play.

(Based on Ainsworth *et al.*, 1978; Krebs & Blackman, 1988)

Table 32.2 Behaviour associated with three types of attachment in one-year-olds using the 'Strange Situation'.

Category	Name	Sample (%)
Type A	**Anxious–avoidant**	**15**

Typical behaviour: Baby largely ignores mother, because of *indifference* towards her. Play is little affected by whether she's present or absent. No or few signs of distress when mother leaves, and actively ignores or avoids her on her return. *Distress is caused by being alone*, rather than being left by the mother. Can be comforted as easily by the stranger as by the mother. In fact, *both adults are treated in a very similar way*.

Type B	**Securely attached**	**70**

Typical behaviour: Baby plays happily while the mother is present, whether the stranger is present or not. Mother is largely 'ignored', because she can be trusted to be there if needed. Clearly distressed when the mother leaves, and play is considerably reduced. Seeks immediate contact with mother on her return, quickly calms down in her arms, and resumes play. The *distress is caused by the mother's absence*, not by being alone. Although the stranger can provide some comfort, *she and the mother are treated very differently*.

Type C	**Anxious–resistant**	**15**

Typical behaviour: Baby is fussy and wary while the mother is present. Cries a lot more than types A and B, and *has difficulty using mother as a safe base*. Very distressed when she leaves, seeks contact with her on her return, but simultaneously shows anger and resists contact (may approach her and reach out to be picked up, then struggles to get down again). This demonstrates the baby's *ambivalence* towards her. Doesn't return to play readily. *Actively resists stranger's efforts to make contact*.

than after the stranger entered or while the mother was absent. However, Ainsworth was particularly fascinated by the unexpected variety of infants' reactions to the mothers' return (*reunion behaviours:* see Table 32.2).

In the SS technique, although every aspect of the participants' reactions is observed and videotaped, it's the child's response to the mother's return that's given the most attention. This provides a clearer picture of the state of attachment than even the response to separation itself (Marrone, 1998).

The dynamics of the attachment relationship can be seen in terms of a balance between (a) exploratory behaviour directed towards the environment, and (b) attachment behaviour directed towards the caregiver. Looked at in this light, securely attached babies have got the balance right (Meins, 2003). But in both patterns of insecure attachment, the balance is tipped to one or other extreme: the anxious-avoidant baby shows high levels of environment-directed behaviour to the detriment of attachment behaviour, while the anxious-resistant baby is

preoccupied with the caregiver to the detriment of exploration and play.

The role of maternal sensitivity

The crucial feature determining the quality of attachment is the mother's *sensitivity*. The sensitive mother sees things from her baby's perspective, correctly interprets its signals, responds to its needs, and is accepting, cooperative, and accessible. By contrast, the insensitive mother interacts almost exclusively in terms of her own wishes, moods, and activities. According to Ainsworth *et al.*, sensitive mothers tend to have babies who are *securely attached,* whereas insensitive mothers have *insecurely attached* babies (either *anxious–avoidant/detached* or *anxious–resistant/ambivalent*).

Both the Uganda and Baltimore studies provided support for the idea that parental sensitivity is the key factor in attachment development. However, they both used rather small samples and so could only be considered promising explorations into the roots of early differences in attachment. But during the past 20 years or so, several studies with larger samples have tested, and supported, the original claim that parental sensitivity actually *causes* attachment security (van Ijzendoorn & Schuengel, 1999).

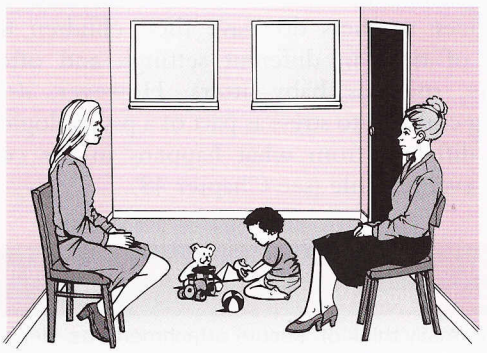


Figure 32.2 One of the eight episodes in the 'Strange Situation'

However, as important as sensitivity is, it isn't an *exclusive* condition for attachment security – other parenting qualities also play a part (e.g. DeWolff & van Ijzendoorn, 1997). Conversely, even abusive parents don't necessarily produce deviant forms of attachment. According to Schaffer (2004), although maltreated children are clearly at risk:

- they usually show some signs of attachment to their abusing parents, although this may be confused and disorganised (see below); the attachment system seems to be so powerful that even in the absence of consistent love and emotional warmth, children persist in trying to form attachments
- there are always some children (although a small minority – about 15 per cent) who form secure attachments; they enjoy good relationships with peers and others, and by no means all abused children become abusing adults.

Evaluation of the Strange Situation

- According to Goldberg (2000) the SS:

> ... represents a unique combination of experimental and clinical methods, as the procedure itself is well standardised but allows controlled opportunities for natural interactions ...

The observer focuses on the infant, with the mother's caregiving behaviour regarded primarily as the *context* for the infant's behaviour. The advantage of this is that while the mother may try to please the experimenter and show herself to be a 'good mother', infant behaviour is free of such biases and is more transparent.

- When the family's living conditions don't change, the children's attachment patterns also remain fairly constant, both in the short term (six months: Waters, 1978) and the long term (up to five years: Main *et al.*, 1985). This is commonly interpreted as reflecting a *fixed characteristic of the child,* such as temperament (see page 542).
- But Vaughn *et al.* (1980) showed that attachment type may change depending on variations in the family's circumstances. Children of single parents living in poverty were studied at 12 and 18 months. Significantly, 38 per cent were classified differently on the two occasions, reflecting changes in the families' circumstances, particularly changes in accommodation and the mothers' degree of stress. This suggests that attachment types aren't necessarily permanent characteristics. In general, the longer the gap between assessments, the more likely it is that children will be found to have changed classification status (Schaffer, 2004).
- Patterns of attachment to mothers and fathers are *independent,* so the same child might be securely attached to its mother, but insecurely attached to its father (Main & Weston, 1981). This shows that attachment patterns derived from the SS reflect qualities of distinct relationships, rather than characteristics of the child. If temperament, for example, were the main cause of attachment classification, the same child should develop the same kind of attachment pattern to both parents (van Ijzendoorn & De Wolff, 1997);
- According to Main (1991; Main & Hesse, 1990), many babies don't fit neatly into Ainsworth *et al*'s three attachment types. She identifies a fourth type, namely *insecure–disorganised/disoriented* (type D). This describes a baby that acts as if afraid of the attachment figure (as well as the environment). Fear usually increases attachment behaviour, which includes seeking closer proximity to the attachment figure. But since the

attachment figure is itself a source of fear, the infant faces a conflict between seeking and avoiding closeness to the attachment figure. Type D has been linked to infant maltreatment or hostile caregiving, maternal history of loss through separation, divorce or death (Lyons-Ruth *et al.*, 1991), and maternal depression (Radke-Yarrow *et al.*, 1995).

CROSS-CULTURAL STUDY 32.2

Cross-cultural studies

Cross-cultural studies have also revealed important differences, both within and between cultures. Van Ijzendoorn & Kroonenberg (1988) carried out a major review of 32 worldwide studies involving eight countries and over 2000 infants, and reached three main conclusions.

1. There are marked differences within cultures in the distribution of types A, B and C. For example, in one of two Japanese studies, there was a complete absence of type A but a high proportion of type C, while the other study was much more consistent with Ainsworth *et al.*'s findings.
2. The overall worldwide pattern, and that for the USA, was similar to the Ainsworth *et al.* 'standard' pattern. But within the USA, there was considerable variation between samples.
3. There seems to be a pattern of cross-cultural differences: while type B is the most common, type A is relatively more common in western European countries, and type C is relatively more common in Israel and Japan.

How can we account for these differences? Regarding the third conclusion, Japanese children are rarely separated from their mothers, so that the departure of the mother is the most upsetting episode in the SS. Japanese mothers commonly sleep with their infants, and are in constant bodily contact with them during the day, carrying them around in slings. As Meins (2003) says:

Constant bodily contact with the mother would make the Strange Situation an extremely stressful way of trying to assess this baby's attachment to her

... in traditional Japanese culture, it would appear that the strange situation is not an appropriate and accurate measure of attachment security, since the procedure is too far removed from the infant's everyday experiences of caregiving ...

For children raised on Israeli kibbutzim (small, close-knit groups), the entrance of a stranger was the main source of distress. Valid interpretations of the SS in cross-cultural settings require intimate knowledge of child-rearing customs and goals (Goldberg, 2000).

While the SS is the most widely used method for assessing infant attachment to a caregiver (Melhuish, 1993), Lamb *et al.* (1985) have criticised it for:

- being highly artificial
- being extremely limited in terms of the amount of information that's actually gathered
- failing to take account of the mother's behaviour.

ASK YOURSELF...

- How could the SS be criticised on ethical grounds?

As we noted earlier, the SS is designed to see how young children react to stress, with the stranger becoming more intrusive over the course of the eight episodes. According to Marrone (1998), although the SS has been criticised for being stressful, it's modelled on common, everyday experiences: mothers do leave their children for brief periods of time in different settings, and often with strangers, such as baby-sitters. However, *deliberately* exposing children to stress as part of a psychological study is very different from what happens in the course of normal, everyday life (see Chapter 48).

CRITICAL DISCUSSION 32.2 Is being securely attached necessarily a good thing?

- We normally think of 'secure attachment' as 'desirable (it's *implicit* in the concept of 'secure').
- But from an *evolutionary* perspective, the variability in types of human attachment pattern prepares the young of the species to adapt to parents' pattern of *investment* in their offspring. Infants increase their chances of survival if they can adapt to the particular caregiving conditions they encounter (Miller, 2002).
- If parents are heavily invested, and so are sensitive and responsive, then environmental risks to the children decrease, and they can explore more freely from their safe base.
- But if parents are unwilling/unable to invest heavily (due to environmental pressures, such as scarce food), then resistant or avoidant attachment styles may be *more adaptive*. In *resistant* attachment, clinging to the caregiver may guarantee whatever meagre resources are available, while in *avoidant* attachment, a more independent child can try to obtain resources from other adults.

- According to Thompson (1998):

  Attachment patterns that are adaptive for certain rearing conditions may be maladaptive for others, and patterns that are initially adaptive may not remain so if conditions change appreciably.

  This relates to cultural differences, and changes in the circumstances of individual families, respectively (see text above).

DEPRIVATION AND PRIVATION

Bowlby's maternal-deprivation hypothesis (MDH)

As noted earlier, Bowlby argued for the existence of a critical period in attachment formation. This, along with his theory of monotropy (see page 546), led him to claim that the mother–infant attachment couldn't be broken in the first few years of life without serious and permanent damage to social, emotional and intellectual development. For Bowlby (1951):

An infant and young child should experience a warm, intimate and continuous relationship with his mother (or permanent mother figure) in which both find satisfaction and enjoyment.

Bowlby's *maternal-deprivation hypothesis* (MDH) was based largely on studies conducted in the 1930s and 1940s of children brought up in residential nurseries and other large institutions (such as orphanages).

KEY STUDY 32.3 Some early research findings on the effects of institutionalisation

Goldfarb (1943): 15 children raised in institutions from about six months until three-and-a-half years of age were matched with 15 children who'd gone straight from their mothers to foster homes. The institutionalised children lived in almost complete social isolation during their first year. The matching was based on genetic factors and natural mothers' education and occupational status.

At age three, the institutionalised group was behind the fostered group on measures of abstract thinking, social maturity, rule-following, and sociability. Between 10 and 14, the institutionalised group continued to perform more poorly on the various tests, and their average IQs (intelligence quotients) were 72 and 95 respectively.

ASK YOURSELF...

- Note that the children weren't assigned randomly to the two 'conditions' (as would happen in a true experiment). So, how was the decision made?
- What characteristics of the children might have determined whether they were fostered or kept in the institution, and how might this have accounted for the results?

Those who appeared to be brighter or more easygoing, more sociable and healthy, were more likely to have been fostered. In this case, the differences in development of the two groups might have been due to these initial characteristics. However, Goldfarb concluded that all the institutionalised children's poorer abilities were due to the time spent in the institutions.

Spitz (1945, 1946); Spitz & Wolf (1946): Spitz found that in some very poor South American orphanages, overworked and untrained staff rarely talked to the infants, hardly ever picked them up even for feeding, gave them no affection, and provided no toys. The orphans displayed *anaclitic depression* (a reaction to the loss of a love object). This involves symptoms such as apprehension, sadness, weepiness, withdrawal, loss of appetite, refusal to eat, loss of weight, inability to sleep, and developmental retardation. It's similar to *hospitalism*.

After three months of unbroken deprivation, recovery was rarely, if ever, complete. In their study of 91 orphanage infants in the USA and Canada, Spitz and Wolf found that over one-third died before their first birthdays, despite good nutrition and medical care.

Interpreting the findings from studies of institutions

Bowlby, Goldfarb, Spitz and Wolf explained the harmful effects of growing up in an institution in terms of what Bowlby called maternal deprivation. In doing so, they failed to:

- recognise that the understimulating nature of the institutional environment, as well as (or instead of) the absence of maternal care, could be responsible for the effects they observed
- disentangle the different types of deprivation and the different kinds of retardation produced (Rutter, 1981)
- distinguish between the effects of deprivation and privation. Strictly, *deprivation* ('de-privation') refers to the loss, through separation, of the maternal attachment figure (which assumes that an attachment has already developed); *privation* refers to the absence of an attachment figure (there's been no opportunity to form an attachment in the first place: Rutter, 1981).

Poor, unstimulating environments are generally associated with learning difficulties and retarded language development. Language development is crucial for overall intellectual development. Hence, a crucial variable in intellectual development is the amount of *intellectual stimulation* a child receives, *not* the amount of mothering.

The studies described in Key Study 32.3 (on which Bowlby originally based his maternal deprivation hypothesis) are most accurately thought of as demonstrating the effects of *privation*. However, Bowlby's own theory and research were mainly concerned with *deprivation*. By only using the one term (deprivation), he

confused two very different types of early experience, which have very different types of effect (both short- and long-term).

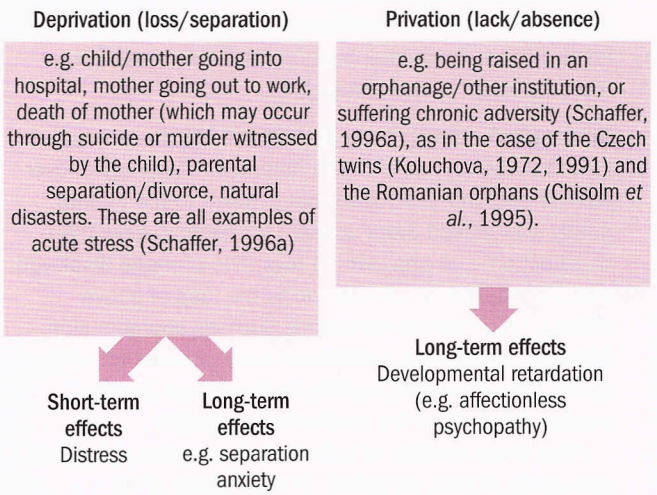

Figure 32.3 Examples of the difference between deprivation and privation, including their effects

Deprivation (separation or loss)

Short-term deprivation and its effects

One example of short-term deprivation (days or weeks, rather than months or years) is that of a child going into a nursery while its mother goes into hospital. Another is that of the child itself going into hospital. Bowlby showed that when young children go into hospital, they display *distress,* which typically involves three components or stages.

Box 32.3 The components or stages of distress

Protest: The initial, immediate reaction takes the form of crying, screaming, kicking, and generally struggling to escape, or clinging to the mother to prevent her from leaving. This is an outward and direct expression of the child's anger, fear, bitterness, and bewilderment.

Despair: The struggling and protest eventually give way to calmer behaviour. The child may appear apathetic, but internally still feels all the anger and fear previously displayed. It keeps such feelings 'locked up' and wants nothing to do with other people. The child may no longer anticipate the mother's return, and barely reacts to others' offers of comfort, preferring to comfort itself by rocking, thumb-sucking, and so on.

Detachment: If the separation continues, the child begins to respond to people again, but tends to treat everyone alike and rather superficially. However, if reunited with the mother at this stage, the child may well have to 'relearn' its relationship with her and may even 'reject' her (as she 'rejected' her child).

Factors influencing distress

ASK YOURSELF...

- Distress (especially protest and despair) can be thought of as an extreme display of attachment behaviour. Looked at this way, what factors do you think are likely to make separation most distressing for a child?

Evidence suggests that not all children go through the stages of distress, and that they differ in how much distress they experience. Separation is likely to be most distressing in the following situations:

- between the ages of 7/8 months (when attachments are just beginning to develop: see page 542) and three years, with a peak at 12–18 months (Maccoby, 1980). This is related to the child's inability to retain a mental image of the absent mother, and its limited understanding of language. For example, because young children cannot understand phrases like 'in a few days' time' or 'next week', it's difficult to explain that the separation is only temporary. They might believe they've been abandoned totally and that they're in some way to blame for what's happened ('Mummy's going away because I've been naughty')
- for boys (although there are also wide differences within each gender)
- if there have been any behaviour problems, such as aggression, that existed before the separation. Such problems are likely to be accentuated if separation occurs

John (17 months) experienced extreme distress while spending nine days in a residential nursery when his mother was in hospital having a second baby. According to Bowlby, he was grieving for the absent mother. Robertson & Robertson (1969) (who made a series of films called *Young Children in Brief Separation*) found that the extreme distress was caused by a combination of factors: loss of the mother, strange environment and routines, multiple caretakers and lack of a mother substitute

- if the mother and child have an extremely close and protective relationship, in which they're rarely apart and the child is unused to meeting new people. Children appear to cope best if their relationship with their mother is stable and relaxed, but not too close, and if they have other attachment figures (such as their father) who can provide love and care. Many institutions used to be run in a way which made the development of substitute attachments very difficult. High staff turnover, a large number of children competing for the attention of a small number of carers, and the sometimes deliberate policies preventing special relationships, could all have worked against the provision of high-quality substitute attachments (Tizard & Rees, 1974).

One *long-term* effect of short-term separation is *separation anxiety.* This is also associated with long-term deprivation and is discussed below.

Long-term deprivation and its effects

Long-term deprivation includes the permanent separation resulting from *parental death,* and the increasingly common separation caused by *divorce.* Perhaps the most common effect of long-term deprivation is what Bowlby called *separation anxiety* (the fear that separation will occur again in the future).

Separation anxiety

Separation anxiety may manifest itself in:

- increased aggressive behaviour and greater demands towards the mother
- clinging behaviour – the child is unable to let the mother out of its sight. This may generalise to other relationships, so that a man who experienced 'bad' childhood separations may be very dependent on, and demanding of, his wife
- detachment – the child becomes apparently self-sufficient, because it cannot afford to be let down again
- some vacillation between clinging and detachment
- psychosomatic (*psychophysiological*) reactions.

The effects of divorce

Divorce isn't a *specific* event, but a long-drawn-out *process* that may impinge on children over a period of years. The process begins with parental conflict, and extends well beyond the departure of one spouse and legal separation (Schaffer, 2004). Children can react very differently at different times, so we mustn't generalise from findings obtained at one particular point in this process.

However, nearly all children (especially boys), regardless of their age, are adversely affected by parental divorce, at least in the short term (Schaffer, 1996a). Yet despite the stresses involved, most children are resilient enough to adapt to their parents' divorce eventually (Hetherington & Stanley-Hagan, 1999). The nature, severity and duration of the effects vary greatly between children. These are influenced by many factors, including:

- continuity of contact with the non-custodial parent
- the financial status/lifestyle of the single-parent family
- whether the custodial parent remarries, and the nature of the resulting step-family.

Box 32.4 Some of the major effects on children of parental divorce

Compared with children of similar social backgrounds whose parents remain married, those whose parents divorce show small but consistent differences throughout childhood. They also have different life courses as they move into adulthood. The differences include:

- lower levels of academic achievement and self-esteem
- a higher incidence (2–3 times) of antisocial and delinquent behaviour, and other problems of psychological adjustment during childhood and adolescence; but only 20–30 per cent of those with maladjustment show any severe or lasting problems
- earlier social maturity, with certain transitions to adulthood (such as leaving home, beginning sexual relationships, cohabiting or getting married and becoming pregnant) typically occurring younger
- a tendency in young adulthood to more frequent changes of job, lower socio-economic status, a greater frequency of depression and lower scores on measures of psychological well-being; they're also more likely themselves to divorce
- more distant relationships in adulthood with parents and other relatives.

(Based on Hetherington & Stanley-Hagan, 1999; Richards, 1995; Schaffer, 2004)

Overall, the risk factor is small, and only a minority of children are affected. According to Schaffer (2004):

... The fear that children are scarred for life by parental divorce is thus not justified as a generalisation.

The findings reported in Critical Discussion 32.3 are *correlational,* so we cannot be sure that it's divorce (or divorce alone) that's responsible for the differences that have been reported.

CRITICAL DISCUSSION 32.3 What is it about divorce that can be harmful?

- According to Schaffer (2004), there are three possible explanations: (a) absence of one of the parents (usually the father); (b) the socio-economic consequences of

living in a single-parent household; and (c) conflict between the parents – before (and sometimes after) the divorce.

- Despite indications that all three play a part in the emergence of psychological difficulties (Amato & Keith, 1991), *conflict* is by far the most potent influence (Schaffer, 1996a).
- Children whose father dies are considerably less likely to be disturbed long term than those who lose their father through divorce. So, it's *not* parental absence as such that's important, rather the *circumstances* surrounding the absence.
- Several follow-up studies have shown that children whose parents divorce are already showing signs of psychological upset as early as 8–12 years *before* the divorce (e.g. Amato & Booth, 1996). This is likely to be the result of the deteriorating nature of the marital relationship and the atmosphere of conflict.
- Conversely, conflict between parents who live together is associated with low self-esteem in children (Amato, 1993). In turn, low self-esteem may lead to other problems, including lower school achievement and difficulties in forming relationships.
- Conflict can have a *direct* influence on the child through witnessing the parents' loss of emotional control. This can be very frightening for young children, at a time when they need parents to provide a model for emotional self-regulation. More *indirectly*, the greater the difficulties between the parents, the greater the difficulties each parent has in caring for the child (Schaffer, 2004).
- Conflict often *increases* in the first few years after divorce, over financial settlements, access arrangements, and co-parenting, parents' rights and responsibilities. Under these conditions, it's better for children to remain in an unhappy two-parent household than to suffer the effects of divorce. If there's a shift to a more harmonious household, then a divorce is advantageous to both boys and girls. But even in low-conflict divorced families, boys (but not girls) are worse off than those in low-conflict non-divorced families (Hetherington & Stanley-Hagan, 1999).

Non-maternal shared care is both historically and culturally normative

whose mothers are employed. For example, just over 52 per cent of women in the UK with children under five worked in 2003 (Hinsliff, 2004). According to Scarr (1998), non-maternal shared care is normative, both historically and culturally (and so is universal).

The demand for child care is driven entirely by the economic need for women in the labour force. In 1997, women comprised 49.5 per cent of those in paid employment in the UK, and in 2000 they outnumbered men (although with a far higher percentage in part-time work: Kremer, 1998).

Despite these changing patterns of female employment, the belief that women are born and reared to be, first and foremost, mothers (the *motherhood mystique/mandate*) remains an influence on our attitudes about working mothers (Kremer, 1998).

ASK YOURSELF...

- What would Bowlby's theory predict about the effects of working mothers on the development of their child's attachment?

The effects of daycare

This is regarded by some as another form of long-term deprivation. According to Scarr (1998), daycare includes all varieties of non-maternal care of children who reside with their parent(s) or close relatives, and so excludes foster care and institutional (residential) care.

A deep-seated and widely held assumption is that child care provided by anyone other than the child's mother is *non-normative* (it's not how most children are cared for). This partly reflects the continuing influence of Bowlby's theory of attachment. However, shared child care is actually a normative experience for contemporary American (and British) children, the vast majority of

According to Bowlby, a child whose mother goes out to work experiences maternal deprivation. If this happens during the child's first year (before an attachment has formed), an attachment may not develop at all (strictly, this is privation). If it happens after an attachment has developed, the child will be distressed, may experience separation anxiety, and so on (see above).

The results have tended to show that there's no weakening of the attachment to the mother resulting from the daily separations involved in daycare. Provided the daycare is *stable* and of a reasonably *high quality,* children don't suffer any ill effects and will benefit from it in certain respects (Schaffer, 1996a).

However, Belsky & Rovine (1988) concluded that infants were more likely to develop insecure attachments if they'd been receiving daycare for at least four months before their first birthday and for more than 20 hours per week. Although many children 'at risk' develop secure attachments, they're also more likely to develop insecure attachments than children who stay at home (see Table 32.2).

However, Belsky and Rovine's findings were obtained exclusively from one method of assessing attachment, namely the SS (see Table 32.1). Clarke-Stewart (1989) argues that this is an inappropriate technique for children in daycare. As we saw earlier, the SS is based on the assumption that repeated separations from the mother put children under stress, and so highlight their attempts at security-seeking. But daycare children are used to such separations and so may not experience stress. When they respond to the mother's return in the SS with (what looks like) indifference, they may be showing independence and self-reliance, not the 'avoidance' or 'resistance' that are used to classify children as insecurely attached (see Critical Discussion 32.2). According to Schaffer (1996a):

It is possible that the Strange Situation procedure is not psychologically equivalent for children of working and of non-working mothers. If that is so, it becomes even more important to ensure that any conclusions are based on a variety of assessment techniques.

ASK YOURSELF...

- If daycare were harmful to young children's attachments, what kind of distribution of secure and insecure attachments would you expect among those whose mothers work compared with those who don't (e.g. what percentage of type A and type C attachments)?

- The observed distribution of insecure infants of working mothers in the USA (22 per cent type A; 14 per cent type C) is virtually identical to the overall distribution for studies around the world (21 per cent and 14 per cent, respectively, based on almost 2000 children of mainly non-working mothers: van Ijzendoorn & Kroonenberg, 1988).
- In theory, an attachment is a relationship, not a global personality trait (see page 549). If the children of working mothers are more insecure with them, this doesn't necessarily mean that they're emotionally insecure in general. We need to assess their emotional health in a range of situations, with a variety of attachment figures. Several studies have shown that children who were in daycare as infants do as well as those who weren't, using measures of security, anxiety, self-confidence and emotional adjustment (Clarke-Stewart, 1989).

CRITICAL DISCUSSION 32.4 To work or not to work?

- As Horwood & Fergusson (1999) point out, much of the research into the effects of daycare has been carried out in the USA. The conclusions from these studies may not apply to other societies and cultures where patterns of maternal, and paternal, participation in the labour force and at home may differ from those in the USA.
- According to Schaffer (2004), it's not the *fact* that mothers work that affects the child (just as it's not divorce as such that's harmful: see above). Rather there's a whole range of factors, such as her ability to cope with her occupational and domestic duties, how much support she receives from her husband/partner and other relatives, her motivations for working and the effect on her self-esteem (as well as the daycare itself) that really make a difference:

  ... What can be safely concluded is that, where conditions are optimal, children of employed mothers may actually benefit compared with those of non-employed mothers, largely as a result of extra experiences with other adults and with peers in day-care settings ... (Schaffer, 2004)

- Even in the early years, 24-hour-a-day mothering needn't be regarded as a necessary prerequisite for healthy psychological development (Gottfried *et al.*, 2002).
- According to Clarke-Stewart (1989):

  Maternal employment is a reality. The issue today, therefore, is not whether infants should be in day care but how to make their experiences there and at home supportive of their development and of their parents' peace of mind.

Privation

As we noted earlier, privation is the failure to develop an attachment to any individual. Given the importance of the child's first relationship as a model or prototype of relationships in general, failure to develop an attachment of any kind is likely to affect adversely all subsequent relationships.

Harlow's research (see above) showed that monkeys brought up with only surrogate mothers were very disturbed in their later sexual behaviour. For example, females had to be artificially inseminated because they wouldn't mate naturally. The unmothered females also became very inadequate mothers, rejecting their infants whenever they tried to cling to their bellies and, literally, walking all over them.

Affectionless psychopathy

According to Bowlby, maternal deprivation in early childhood causes *affectionless psychopathy*. This is the inability to care and have deep feelings for other people and the consequent lack of meaningful interpersonal relationships, together with the inability to experience guilt.

KEY STUDY 32.4 Growing up with TB (Bowlby *et al.*, 1956)

- Bowlby *et al.* studied 60 children aged 7–13 who'd spent between five months and two years in a tuberculosis (TB) sanatorium (which provided no substitute mothering) at various ages up to four.
- About half had been separated from their parents before they were two years old.
- When compared with a group of non-separated 'control' children from the same school classes, the overall picture was that the two groups were more similar than different.
- The separated children were more prone to 'daydreaming', showed less initiative, were more over-excited, rougher in play, concentrated less well, and were less competitive. But they weren't more likely to show affectionless psychopathy, regardless of when their separation had occurred (before or after two).

Bowlby *et al.* admitted that 'part of the emotional disturbance can be attributed to factors other than separation', such as the common occurrence of illness and death in the sanatorium children's families. So, there was very little evidence for the link between affectionless psychopathy and *separation* (or *bond disruption*). However, Bowlby may have provided evidence for an association with privation instead (a failure to form bonds in early life). According to Rutter (1981), privation is likely to lead to:

- an initial phase of clinging, dependent behaviour
- attention-seeking, and uninhibited, indiscriminate friendliness
- a personality characterised by lack of guilt, an inability to keep rules, and an inability to form lasting relationships.

Are the effects of privation reversible?

Suomi & Harlow (1972) found that the effects on rhesus monkeys of being reared in isolation from other monkeys (their mothers or siblings) could be reversed, or at least moderated. This was achieved by allowing them to have extensive contact with 'monkey therapists' (young, normally reared, monkeys). In humans, there are (at least) three kinds of study that demonstrate that it's possible to undo the effects of early privation.

1. *Case studies* of children who've endured extreme early privation, often in near complete isolation. Examples include the Czech twins studied by Koluchova (1972, 1991: see Case Study 32.1) and the concentration camp survivors (Freud & Dann, 1951: see Case Study 32.2).
2. Studies of *late adoption:* children raised in institutions are adopted after Bowlby's critical period for attachment development (12 months for most children, up to two-and-a-half/three years for the rest). Studies include those of Tizard and her colleagues (e.g. Hodges & Tizard, 1989: see Key Study 32.5), and Chisolm *et al.* (1995: see Key Study 32.6).
3. Studies of *developmental pathways* (see page 558).

Studies of extreme privation

This represents the toughest test of the hypothesis that early experience, important at the time, will have long-term effects only if similar experiences occur subsequently (Clarke & Clarke, 2000). What happens to children who suffer extreme early privation but are then 'rescued' and enjoy much improved conditions?

CASE STUDY 32.1 The case of PM and JM (Koluchova, 1972, 1991)

- Identical twin boys, born in 1960 in the former Czechoslovakia, lost their mother shortly after birth. They were cared for by a social agency for a year, then fostered by a maternal aunt for a further six months. They then went to live with their father who'd remarried, but his new wife proved to be excessively cruel to the twins, banishing them to the cellar for the next five-and-a-half years. They were also harshly beaten.
- When discovered in 1967, they were very short in stature, had rickets, no spontaneous speech (communicating largely by gestures), and were terrified of many aspects of their new environment.
- Having been removed from their parents, they first underwent a programme of physical rehabilitation and entered a school for children with severe learning difficulties. They were subsequently adopted by two exceptionally dedicated women.
- Academically, they caught up with their peers and achieved emotional and intellectual normality. At follow-up in 1974 (at age 14), they showed no signs of psychological abnormality or unusual behaviour. They'd gone on to technical school, training as typewriter mechanics, but later went on to further education, specialising in electronics.
- They both had very good relationships with their adoptive mothers, their adopted sisters, and the women's relatives. Both were drafted for national service, and later married and had children. At the age of 29, they were said to be entirely stable, with no abnormalities, and enjoying warm relationships. One had become a computer technician and the other a technical training instructor (Koluchova, 1991).

Clearly, the twins' experience of prolonged privation didn't predestine them to a permanent condition of severe handicap (Clarke & Clarke, 2000).

Like the study of the Czech twins, the fate of the Holocaust survivors seems to highlight the fundamental importance of having *somebody* (not necessarily a mother-figure) with whom to form an emotional bond. According to Tizard (1986), Freud and Dann's study:

... provides ... evidence of the protective function of attachments in development, even when they are not directed to the mother, or indeed to an adult ...

In other words, it's *attachment formation* as such that's important for the development of social and emotional relationships in later childhood and adulthood, rather than who the particular *attachment figure* is.

CASE STUDY 32.2 Childhood survivors of the Holocaust (Freud & Dann, 1951)

- Anna Freud and Sophie Dann studied six German-Jewish orphans rescued from a concentration camp at the end of the Second World War. They'd all been orphaned when a few months old, after which they were kept together as a group in a deportation camp. They were cared for by camp inmates, who were successively deported to Auschwitz. One of the inmates who survived later said, 'We looked after the bodily welfare of the children as much as possible ... but it was not possible to attend to their other needs' (Moskovitz, 1985).
- During their time in the camp, they'd been subjected to many terrifying experiences, including witnessing camp hangings. On release, at age three, all were severely malnourished, normal speech had hardly developed, and they'd developed the same kind of intense attachment to each other that children normally have for their parents – but there was none of the jealousy and rivalry usually found among siblings. They refused to be separated even for a moment, and were extremely considerate and generous to each other. But they showed cold indifference or fearful hostility towards adults. After the camp was liberated, they were flown to Bulldog's Bank in England.
- They obviously cared greatly – and only – for each other. But gradually they began to form attachments to specific adult caretakers, and they showed a spurt in social and language development. In a one-year follow-up, it was clear that they were hypersensitive, aggressive, and difficult to handle. But, as Freud and Dann observe:

  ... they were neither deficient, delinquent nor psychotic. They ... had mastered some of their anxieties, and developed social attitudes. That they were able to acquire a new language in the midst of their upheavals, bears witness to a basically unharmed contact with their environment.

- Within the next two years, all but one of the children had been adopted. All six were traced and interviewed by Moskovitz during 1979 and 1980 (Moskovitz, 1983, 1985). While it had previously been thought that they'd been irreparably damaged:

  What now became apparent ... was the wide range of adaptation when there was theoretically no reason to see anything positive ... Many made adaptations that are not only impressive but inspiring ... (Clarke & Clarke, 2000)

Studies of late adoption

Tizard (1977) and Hodges & Tizard (1989) studied children who, on leaving care between the ages of two and seven, were either adopted or returned to their own families. The institutions they grew up in provided good physical care and appeared to provide adequate intellectual stimulation. However, staff turnover was high, and they operated a policy against allowing strong attachments to develop between the staff and children. Consequently, the children had little opportunity to form close, continuous relationships with adults. Indeed, by age two, they'd been looked after for at least a week by an average of 24 different caregivers. By age four, this had risen to 50. The children's attachment behaviour was very unusual and, in general, the first opportunity to form long-term attachments came when they left the institutions and were placed in families.

By age eight, the majority of the adopted children had formed close attachments to their adoptive parents (who very much wanted a child), despite the lack of early attachments (Tizard & Hodges, 1978). But only some of those children returned to their own families had formed close attachments. The biological parents often had mixed feelings about having the child back, with other children competing for their attention (as well as material hardship). As reported by their parents, the ex-institutional children as a whole didn't display more problems than a comparison group that had never been in care. But their teachers described them as displaying attention-seeking behaviour, restlessness, disobedience and poor peer relationships.

KEY STUDY 32.5 Ex-institution children at age 16 (Hodges & Tizard, 1989)

- At age 16, the family relationships of most of the adopted children seemed satisfactory, for both them and their parents. They differed little from a non-adopted comparison group who'd never been in care. Hence, early institutional care hadn't necessarily led to a later inability to form a close attachment to parents (contrary to Bowlby's predictions).
- By contrast, those children returned to their families still suffered difficulties and poor family relationships. These included mutual difficulty in showing affection, and the parents reported feeling closer to the children's siblings than to the returned children.
- *Outside* the family, however, *both* the adopted and returned children showed similar relationships with peers and adults. Compared with a control group, they were:
  - (a) still more likely to seek adult affection and approval
  - (b) still more likely to have difficulties in their relationships with peers
  - (c) less likely to have a special friend or to see peers as sources of emotional support
  - (d) more likely to be friendly to any peer rather than choosing their friends.

These findings *are* consistent with Bowlby's MDH.

Hodges and Tizard's research indicates that children who fail to enjoy close and lasting relationships with adults in the first years of life can make such attachments later on. But these don't arise automatically, simply by being placed in a family. Rather, they depend on the adults concerned and how they nurture such attachments. Also, if these children experience difficulties in their relationships outside the family, they may have difficulties in future adult relationships and with their own children.

These ex-institution children have now been followed up into adulthood (average age 31 years). This took the form of postal questionnaires (Hodges *et al.*, in preparation; Jewett, 1998), and interviews using the adult attachment interview (see below) with a subsample of the ex-institution group (Williams, 1999).

There were very few significant differences between the ex-institution group and the comparison group, including evidence of psychiatric disorder. However, the former consistently reported difficulties in relationships with friends, partners and children, and significantly greater difficulties in relationships with their families of upbringing. They also reported a tendency to be over-aggressive in their interpersonal relationships, and to be independent and self-reliant.

But they also reported more rewarding intimate friendships, with higher levels of companionship, and higher self-esteem than the comparison group (these differences weren't statistically significant). While acknowledging the small sample size (22 ex-institution, 23 comparisons), Hodges (personal communication, 2000) states that:

> ... the evidence seems to support both the view that the effects of earlier adversity fade given the right later circumstances, and the view that there are some enduring effects producing continuities in personal characteristics.

KEY STUDY 32.6 Late adoption of Romanian orphans (Chisolm *et al.*, 1995)

- Romanian orphans, reared in extremely poor conditions in large-scale institutions, were adopted (by Canadian families) between the ages of eight months and five-and-a-half years
- Even after several years of privation, these children were able to form attachments to their adoptive parents. However, their institutional experience seemed to have left its mark. For example, their behaviour was often described as *ambivalent* (they simultaneously wanted contact and resisted it: see Table 32.2). Also, they weren't easily comforted when distressed.
- Follow-up is needed to see if life in a loving family can eventually overcome this impairment. Based on their intellectual recovery, there are good reasons for being optimistic (Schaffer, 1998).

Developmental pathways

Quinton & Rutter (1988) wanted to find out whether children deprived of parental care become depriving parents themselves. They observed one group of women, brought up in care, interacting with their own children, and compared them with a second group of non-institutionalised mothers. The women brought up in care were, as a whole, less sensitive, supportive, and warm towards their children. This difference could be explained in terms of both:

- various subsequent experiences the women had as a result of their early upbringings (such as teenage pregnancy, marrying unsupportive spouses, and marital breakdown)
- their actual deprived childhoods.

However, there was also considerable variability *within* the group brought up in care, with some women displaying good parenting skills. This could be explained in terms of *developmental pathways* (what Schaffer, 2004, calls *developmental trajectories*). For example, some of the women had more positive school experiences than others. This made them three times more likely as adolescents or young adults to make proper career and marriage partner choices (Rutter, 1989). Such positive experience represents an escape route from the early hardships associated with being brought up in care.

Similar adverse childhood experiences can have multiple outcomes (Schaffer, 1996b, 2004). *Starting off* at a disadvantage doesn't necessarily mean having to *finish up* at a disadvantage. In other words, early disadvantage doesn't inevitably set off a chain reaction of more and

Figure 32.4 A simplified adaptive chain of circumstances in institution-raised women (based on Quinton & Rutter, 1988; Rutter, 1989)

more disadvantage. Periodically, individuals reach *turning points* where choices must be made, and the path that's taken can either reinforce or help to minimise the consequences of previous experience (Schaffer, 2004).

CONTINUITY BETWEEN EARLY AND LATER ATTACHMENT PATTERNS

The effects of early attachments on later adult relationships

Although until recently attachment was studied almost exclusively within parent–child relationships, Bowlby (1977) maintained that 'attachment behaviour is held to characterise human beings from the cradle to the grave'. According to Hazan & Shaver (1987), attachment theory, as developed by Bowlby and Ainsworth in particular, offers a valuable perspective on adult romantic love, helping to explain both positive emotions (caring, intimacy, and trust) and negative emotions (fear of intimacy, jealousy, and emotional 'ups and downs').

Hazan and Shaver were the first to apply Ainsworth *et al.*'s three basic attachment styles to adult–adult sexual/romantic relationships. Their study tried to answer the question: how are *adults'* attachment patterns (in their adult relationships) related to their *childhood* attachments to their parents?

KEY STUDY 32.7 Romantic love conceptualised as an attachment process (Hazan & Shaver, 1987)

- Ainsworth *et al.*'s three attachment styles were 'translated' in a way that would make them suitable for the study of adult attachments. As part of a 'love quiz' in a local newspaper, respondents were asked to indicate which of three descriptions best applied to their feelings about romantic relationships:

Table 32.3 Responses to the question 'Which of the following best describes your feelings?'

Classification	Response	% of respondents
Secure	I find it easy to get close to others and am comfortable depending on them and having them depend on me. I don't worry about being abandoned or about someone getting too close to me	56
Anxious–avoidant	I am somewhat uncomfortable being close to others. I find it difficult to trust them completely, difficult to allow myself to depend on them. I am nervous when anyone gets too close, and often, love partners want me to be more intimate than I feel comfortable being	24
Anxious–ambivalent	I find that others are reluctant to get as close as I would like. I often worry that my partner doesn't really love me or won't want to stay with me. I want to merge completely with another person, and this desire sometimes scares people away	20

- They were also asked to complete a simple adjective checklist describing their childhood relationships with their parents (their recollections of the kind of parenting they received). This was then correlated with their chosen attachment style.

Table 32.4 Correlation between attachment style and type of parenting in adult respondents

Attachment style	Type of parenting
Secure	Readily available, attentive, responsive
Anxious–avoidant	Unresponsive, rejecting, inattentive
Anxious–ambivalent	Anxious, fussy, out of step with child's needs; only available/responsive some of the time.

ASK YOURSELF...

- Compare Hazan and Shaver's findings with those of Ainsworth *et al.*
- Overall, do they match?

The correlations shown in Table 32.4 closely mirror Ainsworth *et al.*'s findings with 12–18-month-olds. Although these results provided encouraging support for an attachment perspective on romantic love, Hazan and Shaver warned against drawing any firm conclusions about the continuity between early childhood and adult experience. It would be excessively pessimistic, at least from the point of view of the insecurely attached person, if continuity were the rule, rather than the exception. The correlations suggest that as we go further into adulthood, continuity with our childhood experiences *decreases*. The average person participates in several important friendships and love relationships, which provide opportunities for revising our *mental models* (or what Bowlby, 1973, called *internal working models*/IWMs) of self and others (see below).

Intergenerational continuity

Another way of looking at the continuity between early and later attachment patterns is to ask how *parents'* attachment styles are related to their *children's* attachment styles. In other words, do people parent their children as they themselves were parented? This is the issue of *inter-*

Rap singer Eminem's lyrics sometimes tell of a very disturbed relationship with his mother. How might this influence his relationship with his own children?

generational continuity (or *intergenerational transfer* of attachment patterns: Meins, 2003).

A commonly used measure of how parents are/were attached to their own parents is the *adult attachment interview* (AAI). Apart from the SS, the AAI is probably the most widely used and best-developed measure of attachment (Goldberg, 2000). It's based on the assumption that what's crucial for predicting parenting behaviour isn't so much the objective facts about our early attachments, but rather how we *construe* these facts, that is, the nature of our IWMs.

Box 32.5 The adult attachment interview (AAI) (Main *et al.*, 1985)

- The AAI is a structured interview, comprising 15 questions designed to tap an individual's experience of attachment relationships in childhood, and how s/he considers those experiences to have influenced later development and present functioning.
- More specifically, for each parent, the person is asked to choose five adjectives which best describe that relationship during childhood. The person then has to illustrate each of these choices by drawing on childhood memories.
- Later, the person is asked how they reacted when upset, to which parent they felt closest and why, whether they ever felt rejected or threatened, why parents may have acted as they did, how these relationships may have changed, and how these earlier experiences (including major loss up to the present time) may have affected their adult functioning and personality.
- Each interview (which lasts about 90 minutes) is classified as a whole, giving an overall 'state of mind' regarding attachment. Four attachment styles are possible:
  - **Secure/autonomous (F):** People with this style discuss childhood experiences openly, coherently and consistently, acknowledging both positive and negative events and emotions. This is the most common style among parents of *securely attached* infants.
  - **Dismissing (D):** These individuals seem cut off from the emotional nature of their childhood, denying especially their negative experiences and dismissing their significance. The importance of attachment experiences is minimised. They appear cooperative, but contradictions make them seem dishonest. This is the most common style among parents of *anxious–avoidant* infants.
  - **Preoccupied/entangled (E):** Such people are overinvolved with what they recollect, appearing so overwhelmed that they become incoherent, confused, even angry. They're still actively trying to please their parents. This is the most common style among *anxious–resistant* infants.
  - **Unresolved/disorganised (U):** This style describes mainly those who've experienced a trauma (which may include physical or sexual abuse), or the early death of an attachment figure, and who haven't come to terms with it or worked through the grieving process (see Chapter 39). This is the most common style among parents of *disorganised* infants.

(Based on Goldberg, 2000; Heard & Lake, 1997; Main *et al.*, 1985; Schaffer, 1996a)

So, the AAI may predict how the mother's child will be attached to her as determined by the SS (Heard & Lake, 1997; Main, 1995). However, it's possible that these findings are affected by the mother's *selective recall:* how she remembers her childhood might be influenced by her *current* experiences with her own child.

ASK YOURSELF...

- How could you try to control this potential confounding variable?

Fonagy *et al.* (1991) tried to rule out this possibility by giving the AAI to 96 women *before* the birth of their children (i.e. during pregnancy), then classifying the children (using the SS) when they were 12 and 18 months old. As Table 32.5 shows, Main *et al.*'s (1985) results (see Box 32.5) were largely replicated (with the exception of the preoccupied mothers). The correlation was especially strong for the autonomous mother–secure child pairing.

These results have been replicated in later studies by Fonagy and his colleagues, for both infant–mother attachment (Fonagy *et al.*, 1994; Steele *et al.*, 1995) and father–infant attachment (Steele *et al.*, 1996). Overall, mothers' perceptions of their own childhood attachments predicted their children's attachments to them 75 per cent of the time. While acknowledging the need to explain the 25 per cent 'failure' rate (Clarke & Clarke, 2000), how can we explain this evidence for intergenerational continuity?

Table 32.5 Mother's prenatal AAI classification and children's Strange Situation classification (based on Fonagy *et al.*, 1991)

	Classification of the mother		
Classification of the children	**Dismissing**	**Autonomous**	**Preoccupied**
Anxious–avoidant	15	8	7
Secure	5	45	5
Anxious–resistant	2	6	3

Inner working models (IWMs)

According to Bowlby (1973), expectations about the availability and responsiveness of attachment figures are built into our IWMs of attachment. These reflect memories and beliefs stemming from our early experiences of caregiving, which are carried forward into new relationships, both during childhood and beyond. They play an active role in guiding perceptions and behaviour.

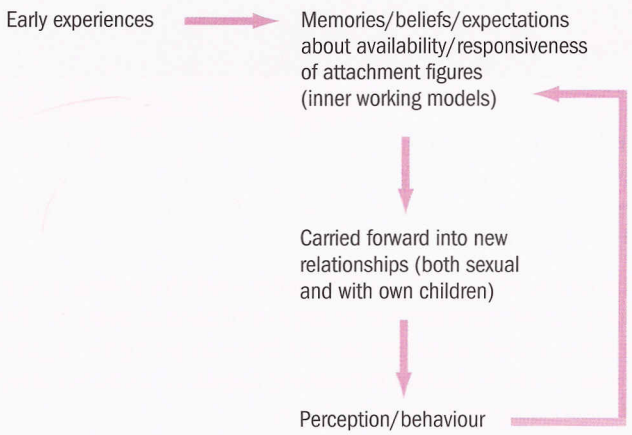

Figure 32.5 How inner working models link early caregiving experiences and later relationships

Bowlby (1973) argued that, at least under normal circumstances, our IWMs are resistant to change:

> Because ... children tend unwittingly to identify with parents and therefore to adopt, when they become parents, the same patterns of behaviour towards children that they have themselves experienced during their own childhood, patterns of interaction are transmitted, more or less faithfully, from one generation to another.

However, IWMs usually can be updated or modified, as new interactions develop. While for young children such change must be based on actual physical events, such direct interaction isn't necessary in older children and adults. Main *et al.* (1985), for example, found that some adults, who reported being insecure in their relationships with their own parents, managed to produce children who were securely attached, at both twelve months and six years. They'd mentally worked through their unpleasant experiences with their parents, and their IWMs were now more typical of secure types (Hazan & Shaver, 1987).

Van Ijzendoorn & Bakermans-Kranenburg (1996) reviewed 33 studies involving the AAI. Similar proportions of mothers, fathers and older adolescents fell into the four attachment categories, but people from lower socio-economic groups were slightly more likely to be classified as dismissing. The largest difference is for people having treatment for mental disorder, who are very unlikely to score as autonomous.

Some mothers who'd had very negative early experiences seemed to have come to terms with them, explaining them in rational terms (such as marital stress, overwork). They were more likely to have secure infants, perhaps because they'd successfully updated their own IWMs. In fact, Bowlby (1988) recognised that attachment behaviour and IWMs *cannot* be regarded as fixed in infancy and unchanging throughout life.

CRITICAL DISCUSSION 32.5 The effects of 'reduced' or 'minimal' parenting

- Due to advances in reproductive technologies, it's become possible for children to be conceived and born 'artificially' to parents who'd otherwise remain childless:
  - *in vitro fertilisation* (IVF) – sperm and egg are provided by the father and mother, but are combined in the laboratory
  - *egg donation* – the father's sperm fertilises another woman's egg, so the child will be genetically related only to him
  - *donor insemination* (DI)/*artificial insemination by donor* (AID) – the mother is impregnated by the sperm of a male other than the husband, so the child will be genetically related only to her.
- Almost 18,000 babies have been born in the UK through donated gametes (sperm and eggs) and embryos since the Human Fertilisation and Embryology Authority (HFEA) was created in 1991. Currently, birth certificates reveal nothing about the genetic father, and the law, as it stands, prevents revelation of the donor's identity. But that's set to change.
- There are various potential problems that may be encountered: the often stressful nature of prolonged fertility treatment, the secrecy surrounding the act of conception, the possibility of tension between the parents because one of them is infertile, as well as that parent's feelings of inadequacy or guilt, children's realisation that they're somehow different, and the absence of a genetic link with one or both parents involved in some of the techniques used (Schaffer, 2004).

ASK YOURSELF...

- What do you think the effects on children brought into the world by such 'unnatural' means might be?

- Golombok and her colleagues (Golombok *et al.*, 1995, 1999, 2001) have conducted some of the few follow-up studies of children conceived in these various ways. They compared families with a child (aged between 4 and 12) conceived by each of the three methods described above with two control groups: (a) naturally conceived children; and (b) children adopted at birth.
- A wide range of measures was used to assess the children's socio-emotional development and cognitive competence. Also, parents were assessed for their warmth, emotional involvement with the child, and the amount of stress they experienced in the course of parenting.
- There was no evidence that these new reproductive technologies have negative consequences – for either child or parent. Neither lack of genetic relationship nor manner of conception had any implications for their well-being.
- Together with studies of adopted children (see above), Golombok's research shows that:

  ... a 'blood-bond' is not necessary for the development of sound parent–child relationships: this can be found even when the role of parenthood is fragmented between a biological and psychological parent ... (Schaffer, 2004)

OTHER ATTACHMENTS

Relationships with siblings

ASK YOURSELF...

- What is it about your relationships with brothers and/or sisters that makes them special?
- Are you closer to one sibling than the others? If so, why?
- If you're an only child, do you feel you've 'missed out'?
- If you're the younger/older of two, how might this have affected your development?

According to Dunn (2000):

... our relationships with our siblings are the longest-lasting we'll probably have – longer than those with our parents or partners, or with our children. Indeed, towards the end of the lifespan, relationships between siblings take on particular importance for many people as sources of support ...

Like friendships (see below), sibling relationships are *horizontal* (Hartup, 1989), that is, reciprocal and egalitarian, while relationships with parents (and other adults) are *vertical*. Children need to experience both types of relationship (Bee, 2000). While relationships with friends and parents seem to be more important for most school-age children than those with their siblings, there's enormous variation.

Box 32.6 Patterns/styles of sibling relationships

Based on direct studies of young children, as well as retrospective reports by young adults about their sibling relationships when they were of school age, several patterns/styles have emerged.

- **Caregiver:** One sibling serves as a kind of quasi-parent for the other. This style is most commonly found between an older sister and younger brother.
- **Buddy:** Both siblings try to be like one another and take pleasure in being together. This is rather more common among pairs of sisters.
- **Critical/conflictual:** One sibling tries to dominate the other, teasing and quarrelling.
- **Rival:** Similar to the critical relationship, but also lacking friendliness or support. This seems to be most common in boy/boy pairs.
- **Casual/uninvolved:** The siblings have relatively little to do with each other.

(Based on Bee, 2000)

Sibling relationships are intense and intimate, and this, together with the significance of sharing parents, means that the relationships have considerable potential for affecting children's wellbeing. For Dunn:

The nature of the sibling relationship – with its uninhibited, no-holds barred expression of negative emotions in many families, and the processes of comparison between siblings – suggests it may well be important in fostering aggression, and in feelings of inadequacy and low self-esteem.

Self-esteem is discussed in Chapter 33. The other side of the coin is that many siblings are extremely affectionate, supportive and companionable. But whatever its emotional colour, the sibling relationship offers children unique opportunities for learning about others and themselves.

Venus and Serena Williams holding the Women's Doubles Trophy at Wimbledon in 2000

Attachment to parents and to siblings

Some studies have found that children who are securely attached to their parents have friendly sibling relationships. But others report findings more consistent with a 'compensatory model', that is, intensely supportive sibling relationships are found in families where the parents are distant and uninvolved with their children. This latter finding is more likely, however, where the family is experiencing extreme stress and relationship difficulties (Dunn, 2000).

Siblings and the development of understanding

The study of siblings has contributed materially to our understanding of children's discovery of the mind (Dunn, 1999: see Chapter 40), including *individual differences.* Children who've engaged frequently in shared pretend play with a sibling, and talked about mental states, are especially successful on tasks that assess understanding of emotion and mental states. Although the data are only correlational:

> ... social processes are likely to play a significant role in shaping the remarkable individual differences in what children understand about others. These differences are linked to moral sensibility and adjustment to school, as well as to relationships with others ... (Dunn, 2000)

Friendships and peer relationships

Attachment and peer relationships

According to Goldberg (2000), the most impressive data on the link between attachment and peer relationships come from the Minnesota longitudinal study (Troy & Sroufe, 1987). Attachment was assessed at 12 and 18 months using the SS, then again at age four, in middle childhood, and at ages 13 and 15.

At age four, *securely attached* children were ranked highest in social competence, were the least isolated and the most popular. They were also the most likely to respond empathically to another child's distress (see Chapter 35), and least likely to be bullies or bullied. *Bullies* were most likely to be classified as *anxious–avoidant,* while victims were most often *anxious–resistant* (see Chapter 29).

In middle childhood, securely attached children were twice as likely as insecure children to form friendships, spend time with a special friend, and become involved in group activities. As adolescents, the securely attached were rated higher on couple relationships and relationships with mixed-sex groups, self-confidence, and showing leadership qualities.

Pre-school friendships

More than 50 per cent of three- and four-year-olds have at least one mutual friend, and most of these friendships last for at least six months (Dunn, 1993; Howes, 1996). Although not nearly as deep or intimate as among school-age or adolescent pairs, these early friendships show more mutual liking and reciprocity, more extended interactions, more positive and less negative behaviour, more forgiveness, and more supportiveness in novel situations than is true of non-friend pairs of the same age. They're also more likely to 'make up' after a quarrel (Dunn, 1993; Hartup *et al.*, 1988). These early friendships are more likely among same-sex pairs.

School-age friendships

Peers become more important at school-age. Among 7–10-year-olds, playing with friends (along with watching TV) takes up almost all the time they're not in school, eating, and sleeping. They centre around shared play interests and activities (rather than shared values or attitudes), and this 'concreteness' is entirely consistent with their self-concept at this age (see Chapter 33) and with their level of cognitive development (see Chapter 34) (Bee, 2000).

Peer-group interests are highly *gender-segregated,* which appears to be a universal pattern. In the case of girls, this may be because they're 'put off' by boys' typical rough-and-tumble style of play and strong emphasis on competition and dominance, and they also find it difficult to influence boys (Maccoby, 1990). But, if anything, boys' same-gender preferences are *stronger* than girls' (Bee, 2000).

Sex differences in friendship quality

According to Waldrop & Halverson (1975), boys' relationships are *extensive,* while girls' are *intensive.* Boys' friendship groups are larger and more accepting of newcomers than girls', and boys play more outdoors. Girls are more likely to play indoors and in smaller groups or pairs, and are less accepting of newcomers (Bee, 2000). The level of competition between pairs of male friends is higher than it is between strangers – the opposite of girls. Girls' friendships also involve more agreement, compliance and self-disclosure.

However, collaborative and cooperative exchanges are the most common forms of communication in both boys' and girls' friendships. These differences may well have enduring implications for patterns of friendship over the entire lifespan (Bee, 2000).

CONCLUSIONS

According to Clarke & Clarke (1998):

> The evidence is firm; while there is a range of outcomes, early social experience by itself does not predestine the future.

Similarly:

> ... the life path is not predetermined by the experiences of the early years alone, but results from the longer-term cumulative development of genetic and environmental interactions and transactions ... (Clarke & Clarke, 2000)

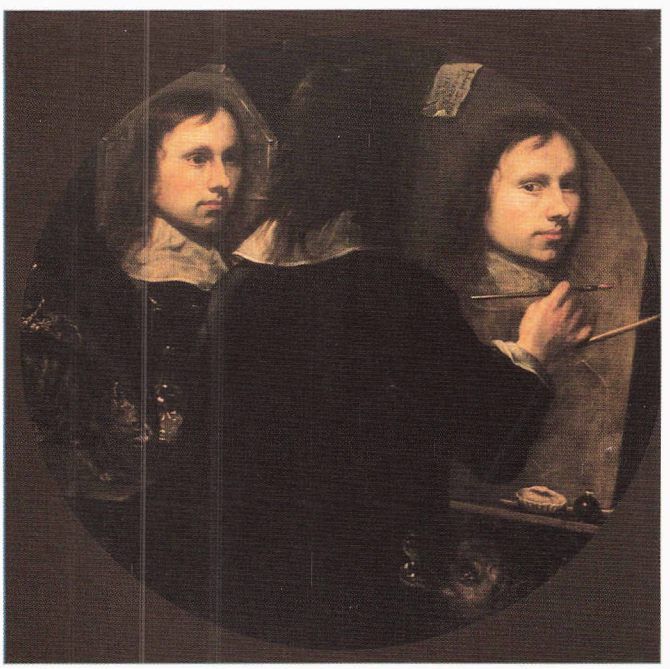
Schaffer (1998) believes that psychological development is far more flexible than was previously thought. Our personalities aren't fixed once and for all by events in the early years. Given the right circumstances, the effects of even quite severe and prolonged deprivation can be reversed. As Clarke & Clarke (2000) conclude:

> ... there is no suggestion that what happens in the early years is unimportant. For most children, however, the effects of such experiences represent no more than a first step in an ongoing life path ... There is little indication that any one point of development is more critical than another; all are important ...

CHAPTER SUMMARY

- **Sociability** is necessary for the development of **attachments**, which are intense, enduring emotional ties to specific people. The **mother–child relationship** is usually taken as a model for all later relationships.
- The attachment process can be divided into **pre-attachment**, **indiscriminate**, **discriminate**, and **multiple attachment phases**.
- The development of specific attachments is shown through **separation anxiety**. Some babies also display the **fear-of-strangers response**.
- According to **'cupboard love' theories**, attachments are learned through satisfaction of the baby's need for food. However, Schaffer and Emerson found that not only were infants attached to people who didn't perform caretaking activities, but those who did weren't always their primary attachment figures.
- According to Bowlby, new-born humans are **genetically programmed** to behave towards their mothers in ways that ensure their survival. There's a **critical period** for attachment development, and attachment to the mother-figure is based on **monotropy**.
- The **Strange Situation** (SS) is used to classify the baby's basic attachment to the mother into three main types: **anxious–avoidant**, **securely attached** and **anxious–resistant**. The crucial feature determining the quality of attachment is the mother's **sensitivity**.
- Patterns of attachment to mothers and fathers are **independent**. Attachment type may change depending on variations in the family's circumstances, and there are also **cultural variations** in the distribution of attachment types.
- Bowlby's **maternal-deprivation hypothesis** (MDH) was used to explain the harmful effects of growing up in institutions. But this fails to recognise the understimulating nature of the institutional environment, and to disentangle the different kinds of retardation produced by different types of **privation**.
- According to Bowlby's theory, **short-term deprivation** produces **distress**. **Privation** produces long-term **developmental retardation** (such as **affectionless psychopathy**).
- Parental death and divorce are examples of **long-term deprivation**, and are associated with long-term effects, particularly **separation anxiety**.
- Children whose parents **divorce** are inevitably adversely affected, both in the short and long term. But most children eventually adapt. **Inter-parental conflict** is the single most damaging factor.
- Provided the **stability** and **quality** of **daycare** are satisfactory, a child's attachment to its mother shouldn't be weakened. Since children in daycare experience regular separations, the SS may be an inappropriate method for assessing their attachments.
- Case studies of children who've endured **extreme privation**, studies of **late adoption**, and Quinton and Rutter's study of **developmental pathways**, all indicate that the effects of early privation are **reversible**.
- There appears to be nothing special about early experiences, and our personalities aren't determined once and for all by early events. The 'same' early experience may have many alternative outcomes.
- **Sibling relationships** are among the most important – and longest-lasting – we experience. They can affect many aspects of development, including aggressiveness, self-esteem, and the understanding of emotion and mental states.
- **Securely attached** infants are more likely to be socially competent and popular with their peers throughout childhood and adolescence. They're also more self-confident and show more leadership qualities.
- **Friendships** become quite common at ages three and four, becoming more important amongst school-age children. Despite some important **gender differences** in friendship quality, **collaboration** and **cooperation** are the most common forms of communication in both boys' and girls' friendships.

Links with other topics/chapters



- Babies' sociability has its adult counterpart in the *need for affiliation*, the basis of *interpersonal attraction* (Chapter 28).
- The pre-attachment phase of attachment development is supported by all the research that demonstrates babies' *preference for human faces* (*facedness*) over aspects of the physical world. This helps to explain the relative ease with which they learn to recognise familiar faces. Also, the baby's ability to imitate facial expressions (Meltzoff & Moore, 1977) may facilitate its relationship with attachment figures (Miller, 2002) (Chapter 16).
- Object permanence (necessary for specific attachments to develop) is part of the *object concept* (Chapter 16) and an important part of the *sensorimotor stage* of Piaget's *theory of cognitive development* (Chapter 34).
- Discussion of fathers as (principal) parents raises some of the same issues as are raised by discussion of *gay and lesbian couples as parents* (Chapter 36).

- The claim that different attachment styles may be *adaptive* in different rearing environments is made by *evolutionary psychologists* (Chapter 2).
- Separation anxiety in the form of psychosomatic (*psychophysiological*) reactions refers to physical symptoms associated with/caused by *stress, anxiety* or other *psychological factors* (Chapter 12).
- The effects of divorce on children include *adolescent* behaviours (such as earlier age of having sex, teenage pregnancies and leaving home) (Chapter 37), earlier age of *cohabitation* and *marriage,* and more distant relationships with parents in *adulthood* (Chapter 38), greater frequency of *depression* (Chapter 44), and higher incidence of *antisocial* and *delinquent behaviour* during childhood and adolescence (Chapter 46).
- The effects on children of daycare is part of a wider debate about the *roles of men and women* and their respective responsibilities for/contributions to child care (Chapter 38).
- An assumption made by many psychologists (and a feature of *social representations* of the effects of early experience: Chapter 22) is that children are highly malleable and their early experiences determine the course of their personality once and for all. Both *Freud* and *Watson* argued that early experience has unique significance (Chapter 2).
- Hazan and Shaver's study can help to explain why some *romantic relationships* last and others don't – in terms of *incompatibility* between partners' attachment styles (Chapter 28).
- The distinction between horizontal and vertical relationships is useful for understanding how the parent–child relationship changes during *adolescence* (Chapter 37).
- *Adolescent peer relationships and friendships* are discussed in Chapter 37.

DEVELOPMENT OF THE SELF-CONCEPT

INTRODUCTION AND OVERVIEW

According to Hampson (1995), the human capacity for self-awareness permits us to try to see ourselves as others see us. When personality psychologists study personality via self-reports, such as questionnaires (see Chapter 42), they're assessing people's perceptions of themselves. Social psychologists also study people's self-perceptions through their study of the *self-concept*.

The self-concept (or simply 'self') is clearly a *hypothetical construct:* it's a 'theory' each one of us develops about who we are and how we fit into society. It's repeatedly revised during childhood in the light of both cognitive development and social experience. On the one hand, as children get older they become more competent at self-awareness and more realistic; on the other hand, other people's perceptions and responses will come to play a more central role in shaping the nature of that awareness (Schaffer, 2004).

Adolescence is a crucial period for the development of the self-concept. A major account of how the self-concept changes in adolescence is Erikson's *psychosocial theory,* which is discussed in Chapter 37. But the formation of the self is never complete. At no time does the self function as a closed system – it's always affected by others' evaluations of us (Schaffer, 2004). This is consistent with the view of the self as 'social to the core' (Fiske, 2004). Even when tracing how self-perception changes in the individual, we'll see that this is an *inherently social process,* as reflected in the early theories of James, Cooley and Mead. More recent extensions of these see the self as *constructed in language* (e.g. Harré).

CONSCIOUSNESS AND SELF-CONSCIOUSNESS

ASK YOURSELF...

- What do you think is the difference between consciousness and self-consciousness?

When you look in the mirror at your face, you're both the person who's looking and that which is looked at. Similarly, when you think about the kind of person you are or something you've done, you're both the person doing the thinking and what's being thought about. In other words, you're both *subject* (the thinker or looker) and *object* (what's being looked at or thought about). We use the personal pronoun 'I' to refer to ourselves as subject, and 'me' to refer to ourselves as object, and this represents a rather special relationship we have with ourselves, namely *self-consciousness/self-awareness.*

While other species possess consciousness (they have sensations of cold, heat, hunger, thirst, and can feel pleasure, pain, fear, sexual arousal, and so on (they're *sentient* creatures), only humans possess self-consciousness. We often use the term 'self-conscious' to describe our response to situations where we're made to feel object-like or exposed in some way (for example, we leave home in the morning to discover our sweater's on back-to-front). But this is a *secondary* meaning: the *primary* meaning refers to this unique relationship in which the same person, the same self, is both subject and object.

What is the self?

'*Self*' and '*self-concept*' are used interchangeably to refer to an individual's overall self-awareness. According to Murphy (1947), 'the self is the individual as known to the individual', and Burns (1980) defines it as 'the set of attitudes a person holds towards himself'.

According to Leary (2004), the self is a *cognitive structure* that permits self-reflection and organises information about oneself. It also has *motivational features,* in particular:

- *self-consistency* (to maintain, if not verify, one's existing view of oneself)
- *self-evaluation* (self-assessment – to see oneself accurately)
- *self-enhancement* (to maintain a positive image of oneself).

One's existing view of oneself is one's *self*-image, and our evaluation of ourselves determines our *self*-esteem. Self-enhancement can be both private and public.

- *Private* self-enhancement also relates to *self-esteem.* According to Greenwald (1980), the *self-esteem motive* acts like a totalitarian political regime which suppresses information and rewrites history to preserve a particular desired image of the government. In the same way, the 'totalitarian ego' distorts facts about the self and rewrites one's memory of personal history in order to maintain one's own positive evaluation.
- *Public* self-enhancement relates to *self-presentation* (or *impression management*), our deliberate attempts to influence others' impressions of us (usually in a positive way: see Chapter 22).

Private vs public self

Murphy's and Burns' definitions of the self are really definitions of the *private* self. According to Leary (2004):

> ... at the most fundamental level, the self is the cognitive apparatus that permits self-reflexive thought – the cognitive structures and associated processes that permit people to take themselves as an object of their own thought and to think consciously about themselves ...

This describes the 'subject'/'object' relationship we discussed above (self-consciousness/awareness) and corresponds to the 'I'/'me' distinction. Leary claims that, strictly, there is only a private self. So, what does the *public* self refer to? It's been used to refer to three distinct entities:

1. the image we convey to others (including reputation and roles)
2. our beliefs about our public image (how we think others perceive us)
3. the impressions others actually form about us.

Whichever of these we mean, the term refers to a very different concept from the private, psychological self,

which allows us to think about and control these public impressions:

> ... this so-called public self resides either within the individual's own private sense of self or in others' minds, respectively. In either case, it is not a 'self' in the true sense of the term ... (Leary, 2004)

However, both Goffman's (e.g. 1971) *dramaturgical* approach, and the *social constructionist* approaches reject the view of the self as a private feature of individuals, seeing it as wholly *social/public* (see below).

Components of the self-concept

The self-concept is a general term that normally refers to three major components: *self-image, self-esteem,* and *ideal self.*

Self-image

ASK YOURSELF...

- Give 20 different answers to the question 'Who am I?'

Self-image refers to the way we describe ourselves, what we think we're like. One way of investigating self-image is to ask people the question 'Who am I?' 20 times (Kuhn & McPartland, 1954). This typically produces two main categories of answer.

1. *Social roles* are usually objective aspects of the self-image (e.g. son, daughter, brother, sister, student). They are 'facts' that can be verified by others.
2. *Personality traits* are more a matter of opinion and judgement, and what we think we're like may be different from how others see us. But how others behave towards us has an important influence on our self-perception (see below).

As well as social roles and personality traits, people's answers often refer to their *physical characteristics* (such as tall, short, fat, thin, blue-eyed, brown-haired). These are part of our *body image/bodily self,* the 'bodily me' which also includes bodily sensations, such as pain, cold and hunger. A more permanent feature of our body image relates to what we count as part of our body (and hence belonging to us), and what we don't.

Allport (1955) gives two rather dramatic examples of how intimate our bodily sense is, and just where we draw the boundaries between 'me' and 'not me'.

ASK YOURSELF...

- Imagine swallowing your saliva – or actually do it. Now imagine spitting it into a cup and drinking it. Clearly, once we've spat out our saliva, we've disowned it – it no longer belongs to us!
- Imagine sucking blood from a cut on your finger (something we do quite automatically). Now imagine sucking the blood from a plaster on your finger! Again, once it's soaked into the plaster it has ceased to be part of ourselves.
- Can you think of any exceptions to this 'rule'?

Simon Weston, survivor – and casualty – of the Falklands War in 1982

We might feel we've lost part of ourselves when we have very long hair cut off, and lovers often keep locks of each other's hair as constant (and tangible) reminders that the other exists. Whenever our body changes in some way, so our body image changes. In extreme cases (such as losing a limb, being scarred, or having cosmetic surgery), we'd expect a correspondingly dramatic change in body image.

Self-esteem

While the self-image is essentially *descriptive,* self-esteem (or *self-regard*) is essentially *evaluative.* It refers to how much we like and approve of ourselves, how worthy a person we think we are. Coopersmith (1967) defined it as 'a personal judgement of worthiness, that is expressed in the attitudes the individual holds towards himself'.

How much we like or value ourselves can be an overall judgement, or it can relate to specific areas of our lives. For example, we can have a generally high opinion of ourselves and yet not like certain of our characteristics or attributes (such as our curly hair when we want it straight, or our lack of assertiveness when we want to be more assertive). Conversely, it may be very difficult to have high overall esteem if we're very badly disfigured, or are desperately shy.

Box 33.1 Different domains of self-esteem (Harter, 1999)

Harter believes that there are five separate areas/domains involved in assessing children's self-esteem.

1. **Scholastic competence:** how able the child considers him/herself at school work.
2. **Athletic competence:** how able the child considers him/herself at sport.
3. **Social acceptance:** whether the child feels popular with his/her peers.
4. **Physical appearance:** how good-looking the child believes him/herself to be.
5. **Behavioural conduct:** to what extent the child considers his/her general behaviour to be acceptable to others.

These five domains are combined to make a single assessment tool, the *Self-Perception Profile for Children* (S-PPC). A *global self-worth scale* is included, which asks how much children like themselves as people. Profiles can be consistently high, consistently low, or can vary across domains.

ASK YOURSELF...

- How many, and which, of these domains apply to adolescents and adults?
- Do more domains have to be added as we get older? If so, what might they be?

Our self-esteem can be regarded as how we evaluate our self-image, that is, how much we like the kind of person we think we are. Clearly, certain characteristics or abilities have a greater value in society generally, and so are likely to influence our self-esteem accordingly (for example, being physically attractive as opposed to unattractive: see Chapter 28). The value attached to particular characteristics will also depend on culture, gender, age and social background (see Critical Discussion 33.2, page 572).

CRITICAL DISCUSSION 33.1 Is self-esteem all it's cracked up to be?

- According to Fiske (2004), the benefits of high self-esteem are real, but they can be taken too far:

  ... Nowadays, self-esteem is all the rage, as attested by the self-help section of the nearest bookstore: Self-esteem is the great cure-all, the great panacea for the problems that ail us ...

- But Baumeister (1998) has begun to debunk this myth – in the context of violence and aggression. In a review of the research literature, Baumeister *et al.* (1996) concluded that some of the most aggressive people have incredibly *high* self-esteem. Violence becomes more likely when another person or situation contradicts a person's highly favourable view of oneself.
- Such individuals' self-esteem is also *fragile* and *inflated*. It's this combination that makes them so easily threatened. Violence and aggression may be an attempt at self-protection. Murder, rape, assault and domestic violence are often associated with threats to honour and feelings of male superiority.

Ideal self

Self-esteem is also partly determined by how much the self-image differs from the *ideal self*. If our self-image is the kind of person we think we are, then our ideal self (*ego-ideal* or *idealised self-image*) is the kind of person we'd *like to be*. This can vary in extent and degree. We may want to be different in certain aspects, or we may want to be a totally different person. (We may even wish we were someone else!) Generally, the greater the gap between our self-image and our ideal self, the lower our self-esteem (see Rogers' *self theory:* Chapter 42).

Self-schemata

We not only represent and store information about other people, we do so about ourselves – but in a more complex and varied way. This information about the self constitutes the self-concept. We tend to have very clear conceptions of ourselves (*self-schemata*) on some dimensions (such as those that are very important to us), but not others. For example, if you think of yourself as athletic, as

Jocelyne Wildenstein (the 'Cat Woman') has had several plastic surgery procedures to make herself look like a cat

definitely not unathletic, and being athletic is important to you, then you are *self-schematic* on that dimension (it is part of your self-concept: Hogg & Vaughan, 1995).

ASK YOURSELF...
- What are you self-schematic on?

Most people have a complex self-concept with a relatively large number of self-schemata. These include an array of *possible* selves, *future-oriented* schemata of what we'd like to become (ideal self) (Markus & Nurius, 1986). Visions of future possible selves may influence how we make important life decisions, such as career choice.

The idea of *multiple selves* raises the question of whether there's any one self that's more real or authentic than the others. For example, perhaps we feel most real (most 'ourselves') when with someone we believe sees us as we wish to be seen. Personality theorists tend to assume that the person has a single, unitary self. This is implied by the fact that typical instructions at the top of a personality questionnaire don't specify which self the respondent should describe (Hampson, 1995). By contrast, social psychologists recognise the possibility that the self refers to a complex set of perceptions, composed of a number of schemata relating both to what we're like and how we *could be.*

THEORIES OF SELF

James' theory: self-as-subject/self-as-object

It was James (1890) who first made the distinction between *self-as-subject or knower* ('I') and *self-as-object or known* ('me'). The 'I' represents the principal form of the self, lying at the centre of our state (or 'stream') of consciousness. But we have as many selves as we have social relationships: the self is *multifaceted.* This is consistent with the widely shared view that we modify our behaviour to some extent depending on whom we're with: different others bring out different aspects of our personality (Hampson, 1995).

Goffman's dramaturgical theory

James' view of multiple selves is also consistent with Goffman's (1971) account of *self-presentation,* which he defined as the creation and maintenance of a *public self.* By analogy with the theatre, each participant in a social interaction is engaged in a performance designed as much for its effect on the audience as it is for honest and open expression of the self. Indeed, according to this *dramaturgical approach,* personality is equated with the various roles the person plays in life.

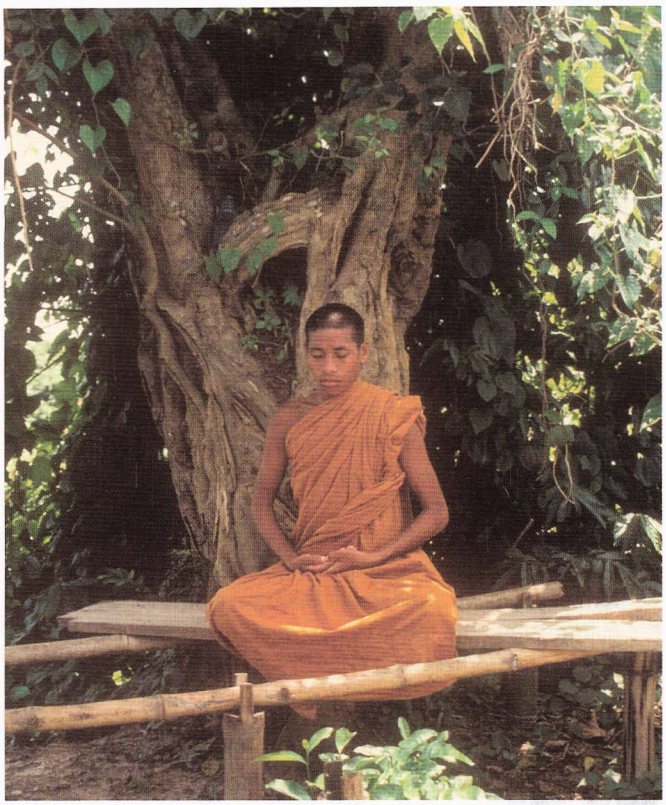
So, for Goffman (1971), the only true self is a public one. In discussing the link between self and self-presentation, he says:

> A correctly staged and performed scene leads the audience to impute a self to a performed character, but this impression – this self – is a *product* of a scene that comes off and is not a *cause* of it. The self shouldn't be regarded as an internal, organic thing, but rather as the dramatic effect of a person's public presentation.

James' idea of multiple selves goes much further than this, by suggesting that different personalities are constructed in the context of every relationship one has (Hampson, 1995).

ASK YOURSELF...
- Do you agree with James or Goffman, or do you believe there is just one 'self', that remains constant regardless of whom we're interacting with or the context of the interaction?

Cooley's theory: the looking-glass self



According to Cooley's (1902) *theory of the looking-glass self,* the self is reflected in the reactions of other people, who are the 'looking-glass' for oneself. That is, in order to understand what we're like, we need to see how others see us, and this is how children gradually build up impressions of what they're like. We receive reflections of judgements and evaluations of our behaviour and appearance, which produce some form of self-feeling (such as pride or shame).

Consistent with the notion of multiple selves, Cooley claims that the looking-glass isn't a 'mere mechanical reflection', because it will differ depending on whose view we take. The individual and society are opposite sides of the same coin (Denzin, 1995).

Mead's symbolic interactionism

Symbolic interactionism is mainly associated with Mead (1934), who was influenced by the earlier theories of James and Cooley. According to symbolic interactionism, human beings act towards things in terms of their *meanings.* People exist in a *symbolic* as well as a physical environment: the importance of a social interaction is derived from the meaning it holds for the participants. The 'interaction' refers specifically to the fact that people communicate with each other, which provides the opportunity for meanings to be learned. Because we share a common language and have the ability for symbolic thought, we can (at least in principle) look at the world from the point of view of other perceivers – that is, *take the role of the other.* According to Mead, this is essentially the process by which the self develops.

Mead turned James and Cooley on their heads. The self isn't mentalistic (something privately going on inside the individual) but, like mind, is a cognitive process lodged in the *ongoing social world.* However, like Cooley, he saw self and society as two terms in a reciprocal

Buddhist monk in meditation

process of interaction (Denzin, 1995). Knowledge of self and others develops simultaneously, both being dependent on social interaction: self and society represent a common whole and neither can exist without the other.

According to Mead, the human being is an organism with a self. This converts him into a special kind of actor, transforms his relation to the world, and gives his actions a unique character. The human being is an object to himself, that is, he can perceive himself, have conceptions about himself, communicate with himself and so on. In sum, he can interact with himself, and this self-interaction is a great influence upon his transactions with the world in general, and with other people in particular.

Self-interaction is a *reflexive process,* which is Mead's way of making the 'I'/'me' distinction. The experiencing 'I' cannot be an object, it cannot itself be experienced, since it's the very act of experiencing. What we experience and interact with is our 'me'.

As important as language is in (self-)interaction, the *key process* by which we develop a concept of self is *role-taking.* By placing ourselves in the position of others, we can look back on ourselves. The idea of self can develop only if the individual can 'get outside himself (experientially) in such a way as to become an object to himself' (Mead, 1934); that is, to see ourselves from the standpoint of others.

Box 33.2 Mead's developmental theory of the self

- Initially, the child thinks about his conduct as 'good or bad only as he reacts to his own acts in the remembered words of his parents'. 'Me' at this stage is a combination of the child's memory of his own actions and the kind of reaction they received.
- In the next stage, the child's pretend play, in particular 'playing at mummies and daddies' or 'doctors or nurses', helps the child to understand and incorporate adult attitudes and behaviour. Here, the child isn't merely imitating but also 'calls out in himself the same response as he calls out in the other'. For example, he's being the child and the parent and, as the parent, is responding to himself as the child. So, in playing with a doll, the child 'responds in tone of voice and in attitudes as his parents respond to his cries and chortles'.
- Play is distinguished from games, which involve rules: 'The child must not only take the role of the other, as he does in the play, but he must assume the various roles of all the participants in the game, and govern his action accordingly...'. Games are a later development than play.
- In this way, the child acquires a variety of social viewpoints or 'perspectives' (mother, father, nurse, doctor), which are then used to accompany, direct and evaluate his own behaviour. This is how the *socialised part of the self* (Mead's 'me') expands and develops.
- At first, these viewpoints or perspectives are based upon specific adults. But in time, the child comes to react to himself and his behaviour from the viewpoint of a 'typical mother', a 'typical nurse' or 'people in general' (the *generalised other*). The incorporation of the generalised other marks the final, qualitative change in the 'me'. 'It is this generalised other in his experience which provides him with a self.'
- Grammatically, our 'me' is third person (like 'she' or 'he'), and it's an image of self seen from the perspective of a judgemental, non-participant observer. By its very nature, 'me' is social, because it grows out of this role-playing, whereby the child is being the other person.

(Based on Mead, 1934)

Social constructionist approaches

Influenced by Mead, many sociologists and social psychologists see the role of language as fundamental to the construction and maintenance of the self. What we say about ourselves often depends on who's listening. In selecting what to say and not to say, we're actively *constructing* a self in relation to another person: we're constantly 'making a self'. The self is not a static, internal entity but a constantly changing *process* (Petkova, 1995).

According to Harré (1985, 1989), our understanding and experiences of ourselves as human beings, our subjective experiences of selfhood, are laid down by the

beliefs about being a person that are implicit in our language. The structure of our language implies certain assumptions/beliefs about human nature, which we live out in our daily interactions with others. For example, the words 'I' and 'me' mislead us into believing that each of us is represented by a coherent, unified self which operates mechanisms and processes (the subject matter of psychology) that are responsible for our actions. But 'self', 'ego', 'mind' and so on don't refer to anything that exists objectively in the world: they're *hypothetical constructs* which perform the very important function of helping us to organise and structure our world (Burr, 1995).

According to Harré (1995c; 1999), what 'I' actually does is specify a location for the acts performed by a speaker. It draws attention to the body of one particular speaker who occupies a unique location, both physically and socially. It also commits that individual to the *consequences* of his/her utterance. We use words such as 'I' in conversation to perform actions in a *moral universe:*

> ... 'I' ... is a form of life, a moral community that has been presupposed by the uses of the first person, not a kind of hidden inner cognitive engine ... (Harré, 1989)

Similarly, Potter & Wetherell (1987) argue that the very experience of being a person, the kind of mental life one can have, perhaps even how we experience sensory information, are dependent on the particular representations of selfhood, the particular ways of accounting for/talking about ourselves, that are available in our culture. These 'stories' or accounts, whose meaning is shared by members of a culture, are called *discourses.* Since these differ from culture to culture, it follows that members of different cultures will experience being human ('selves') in different ways.

CRITICAL DISCUSSION 33.2: The self-concept as a cultural phenomenon

- In Maori culture, the person is invested with a particular kind of power (*mana*), given by the gods in accordance with the person's family status and birth circumstances. This is what enables the person to be effective, whether in battle or everyday dealings with others.
- But this power isn't a stable resource, and can be increased or decreased by the person's day-to-day conduct. For example, it could be reduced by forgetting a ritual observance, or committing some misdemeanour.
- People's social standing, and successes and failures, are seen as dependent on external forces, not internal states (such as personality or level of motivation). In fact, *mana* is only one of these external forces which inhabit the individual.
- People living in such a culture would necessarily experience themselves quite differently from what people in western culture are used to. Instead of representing themselves as the centre and origin of their actions, which is crucial to the western concept of the self:

  > *The individual Maori does not own experiences such as the emotions of fear, anger, love, grief; rather they are visitations governed by the unseen world of powers and forces ... (Potter & Wetherell, 1987)*

- According to Moscovici (1985), 'the individual' is the greatest invention of modern times. Only recently has the idea of the autonomous, self-regulating, free-standing individual become dominant, and this has fundamental implications for the debate about free will and determinism (see Chapter 49).
- Smith & Bond (1998) argue that we need to distinguish between *independent* and *interdependent* selves: the former is what's stressed in western, *individualist* cultures, and the latter by non-western, *collectivist* cultures (see Chapter 47).

An evaluation of social constructionist approaches

- According to Burr (2003):

  > The idea of self does not dictate any particular content to that concept. The fact that our western concept of self contains such things as personality, individuality and agency can be accounted for, in social constructionist terms, by prevailing discourses. But the fact that we have a concept of self at all cannot ...

  In other words, Burr seems to be saying that the *concept* of self is *universal.*

- According to Willig (2001), discursive psychology's rejection of subjectivity, self-awareness, thought, intentions and sense of life history (in other words, 'self') has left a gaping hole in social constructionist psychology. If 'self' is merely a *linguistic phenomenon,* fragmented and distributed across discourses and interactions, social constructionists haven't replaced it with anything that performs its *explanatory function.*
- Burr (2003) believes that 'personality', 'attitudes' and other 'contents' of the person can be dispensed with, but the concept of self can be reclaimed by social constructionist psychologists without compromising their theoretical assumptions. Unlike mainstream psychology's 'humanistic' self, the social constructionist self isn't fixed and doesn't have to be seen as causing anything:

  > ... human beings always will be conscious of selfhood. The only thing this is contingent upon is social interaction. Human beings become persons when they become engaged in social encounters, and this makes some form of selfhood

possible and even inevitable. My self-concept arises out of reflection, and is present during all social interactions, in effect constituting a third 'other' that exerts the same pull on my conduct as real interactants ... (Burr, 2003)

◎ As Harré acknowledges (see above), the self grounds moral choices and agency. Without it, it's hard to see how we can avoid regarding all actors as interchangeable. Where do moral choices come from? According to Burr (2003), Mead's *generalised other* is crucial here: the other is so much part of my make-up that my experience isn't differentiated from the other's. We intuitively feel the consequences of our actions, because we're not differentiated from the other.

FACTORS INFLUENCING THE DEVELOPMENT OF THE SELF-CONCEPT

Much of the research into factors that influence the self-concept can be understood in relation to the symbolic interactionist position. But the importance of these factors extends beyond childhood – our self-concept is constantly being revised. The most significant 'change' is probably the time when it's first being formed.

Argyle (1983) identifies four major influences:

1. the reaction of others
2. comparison with others
3. social roles
4. identification (see Chapters 35 and 36).

The reaction of others

We've already seen in the theories of Cooley and Mead how central the reactions of others are in the formulation of our self-concept. Any attempt to explain how we come to be what we are, and how we change, involves us in the question of what kind of evidence we use. Kelly (1955), like Cooley and Mead, believes that we derive our pictures of ourselves through what we learn of other people's pictures of us (see Chapter 42). So, the central evidence is the reaction of others to us, both what they say of us and the implications of their behaviour towards us. We filter others' views of us through our views of them. We build up continuous and changing pictures of ourselves out of our interaction with others.

Guthrie (1938) tells the famous story of a dull and unattractive female student. Some of her classmates decided to play a trick on her by pretending she was the most desirable girl in the college, and drawing lots to decide who would take her out first, second and so on. By the fifth or sixth date, she was no longer regarded as dull and unattractive.

ASK YOURSELF...
- Try to explain this change in the student.

Teachers – major new significant others for younger children

By being treated as attractive she had, in a sense, *become* attractive (perhaps by wearing different clothes and smiling more), and her self-image had clearly changed. For the boys who dated her later, it was no longer a chore! 'Before the year was over, she had developed an easy manner and a confident assumption that she was popular' (Guthrie, 1938).

Preschool children are extremely concerned with how adults view them, and few things are more relevant than the reactions to them of *significant others* (parents, older siblings, and other people whose opinions the child values). Strictly speaking, it's the child's *perception* of others' reactions that makes such an important contribution to how the child comes to perceive itself. After all, the child has no frame of reference for evaluating parental reactions: parents are all-powerful figures, and what they say is 'fact'. If a child is consistently told how beautiful she is, she'll come to believe it (it will become part of her self-image). Similarly, if a child is repeatedly told how stupid or clumsy he is, this too will become accepted as the 'truth', and the child will tend to act accordingly.

The first child is likely to develop high self-esteem and the second low self-esteem. Argyle explains this in terms of *introjection* (a process very similar to identification), whereby we come to incorporate into our own personality the perceptions, attitudes and reactions to ourselves of our parents. It's through others' reactions that the child learns its *conditions of worth,* that is, which behaviours will produce *positive regard* and which will not (Rogers, 1959: see Chapter 42).

When the child starts school, the number and variety of significant others increase to include teachers and peers. At the same time, the child's self-image is becoming more differentiated, and significant others then become important in relation to different parts of the self-image. For example, the teacher is important as far as the child's

academic ability is concerned, parents as far as how loveable the child is, and so on.

How others' reactions influence self-esteem

KEY STUDY 33.1 The development of self-esteem (Coopersmith, 1967)

- From an original sample of hundreds of 9- and 10-year-old white, middle-class boys, Coopersmith selected five groups (17 per group), including those who scored high, and those who scored low, on each of three measures of self-esteem:
  - a his self-esteem inventory
  - b teachers' evaluations of the boys' reactions to failure, self-confidence in new situations, and so on
  - c scores on the thematic apperception test (TAT) (see Chapter 9, page 153).
- The *high-esteem* boys were confident about their own perceptions and judgements, expected to succeed at new tasks and to influence others, and readily expressed their opinions. They were also doing better in school and were more often chosen as friends by other children than the low-esteem boys. They had a realistic view of themselves and their abilities, weren't unduly worried by criticism, and enjoyed participating in things.
- The *low-esteem* boys were a 'sad little group', isolated, fearful, reluctant to join in, self-conscious, oversensitive to criticism, consistently underrating themselves, tending to underachieve in class, and preoccupied with their own problems.
- But there were no significant differences in intelligence or physical attractiveness between the two groups, who were all free from any obvious emotional disturbance.
- Based on a questionnaire and in-depth interviews with the mothers, plus interviews with the boys about their parents' childrearing methods, Coopersmith found significant differences between the two sets of parents.
- The optimum conditions for the development of high self-esteem seem to involve a combination of firm enforcement of limits on the child's behaviour, plus a good deal of acceptance of the child's autonomy and freedom within those limits. Firm management helps the child to develop firm inner controls: a predictable and structured social environment helps the child to deal effectively with the environment, and hence to feel 'in control' of the world (rather than controlled by it).
- Coopersmith followed the boys through into adulthood, and found that the high-esteem boys consistently outperformed the low-esteem boys and proved more successful – educationally and vocationally.

ASK YOURSELF...

- Can you think of any limitations of Coopersmith's study that would make it difficult to generalise the results?

An evaluation of Coopersmith's study

- Coopersmith's data are only *correlational,* so we cannot be sure that how the boys were raised was actually responsible for their level of self-esteem. Remember, too, that the boys were white middle-class and therefore not representative of the American population as a whole – what about working-class, black and female children?
- Generally, girls have lower self-esteem than boys. For example, when paired with boys in problem-solving tasks, they sometimes artificially depress their performance so as not to outshine their male partners (boys very rarely do this!). Some girls seem to feel uncomfortable in the superior role, as if this is inconsistent with their 'true' position in life. They also tend to rate themselves less highly than boys on written tests of self-esteem, set themselves lower goals in life, and are more inclined to underestimate their abilities than boys, even in primary school, where in reading and language skills they often tend to surpass boys (see Chapter 36).

Box 33.3 The schizophrenic self

- In contrast with the parents of high-esteem boys in Coopersmith's study is the study of interaction between parents and their schizophrenic children.
- These parents tend to deny *communicative support* to the child, and often fail to respond to the child's statements and demands for recognition of its opinions. When the parents do communicate with the child, it's often in the form of an interruption or an intrusion, rather than a response to the child. In fact, they respond selectively to those of the child's utterances that they themselves have initiated, rather than those initiated by the child.
- Laing (1970) suggests that these kinds of communication patterns within the family make the development of *ego boundaries* in the child very difficult – that is, there's a confusion between *self* and *not-self* (me and not-me). This impaired autonomy of the self and appreciation of external reality are often found to be fundamental characteristics of schizophrenic adolescents and adults (see Chapter 44).

Comparison with others

ASK YOURSELF...

- Can you think of any examples of where comparison with others (either made by others or yourself) has affected your self-image/self-esteem (either favourably or unfavourably)?

According to Bannister & Agnew (1976), the personal construct of 'self' is intrinsically *bipolar* – that is, having a

concept of self implies a concept of not-self. (This is similar to Cooley and Mead's view that self and society are really two sides of a coin.) So, one way in which we come to form pictures of what we're like is to see how we compare with others. Indeed, certain components of self-image are meaningful only through comparison with others. For example, 'tall' and 'fat' aren't absolute characteristics (like, say, 'blue-eyed'): we're tall or fat only in relation to others who are shorter or thinner than us. This is true of many other characteristics, including intelligence (see Chapter 41).

Parents and other adults often react to children by comparing them with other children (such as siblings: see Chapter 32). If a child is told repeatedly that she's 'less clever than [her] big sister', she'll come to incorporate this into her self-image, and will probably have lower self-esteem as a result. This could adversely affect her academic performance, so that she doesn't achieve in line with her true ability. A child of above average intelligence who's grown up in the shadow of a brilliant brother or sister may be less successful academically than an average or even below average child who's not had to face these unfavourable comparisons.

ASK YOURSELF...

- Do you think it's possible for the converse to be true – in other words, can one's view of self affect how we compare ourselves with others?

According to Tesser (2004), recent research has demonstrated exactly this effect. For example, the poorer our performance in, say, athletics, the more charitable we are in evaluating others' athletic performance. If I do poorly, then others who do poorly are 'OK'; if I do well, then people who do poorly are rated down. Under some conditions, when we're outperformed by others, we *don't* downgrade our view of self but, instead, upgrade their performance (Alicke *et al.*, 1997). It's less threatening to be outperformed by a 'genius' than someone of normal/average ability (they're 'out of our league').

Social roles

As we noted earlier, social roles are what people commonly regard as part of 'who they are'. Kuhn (1960) asked seven-year-olds and undergraduate students to give 20 different answers to the question, 'Who am I?' The seven-year-olds gave an average of five answers relating to roles, while the undergraduates gave an average of ten. As we get older, we incorporate more and more roles into our self-image, reflecting the increasing number and variety of roles we actually take on. The preschooler is a son or daughter, perhaps a brother or sister, has other familial roles, and may also be a friend to another child. But the number and range of roles are limited compared with those of the older child or adult.

DEVELOPMENTAL CHANGES IN THE SELF-CONCEPT

How do we get to know ourselves?

Achieving identity, in the sense of acquiring a set of beliefs about the self (a *self-schema*), is one of the central developmental tasks of a social being (Lewis, 1990). It progresses through several levels of complexity, and continues to develop through the lifespan (see Chapters 38 and 39).

During the first few months, the baby gradually distinguishes itself from its environment and from other people, and develops a sense of *continuity through time* (the *existential self*). But at this stage, the infant's self-knowledge is comparable to that of other species (such as monkeys). What makes human self-knowledge distinctive is becoming aware that we have it – we're conscious of our existence and uniqueness (Buss, 1992).

According to Maccoby (1980), babies are able to distinguish between themselves and others on two counts:

1. their own fingers hurt when bitten (but they don't have any such sensations when they're biting their rattle or their mother's fingers)
2. probably quite early in life, they begin to associate feelings from their own body movements with the sight of their own limbs and the sounds of their own cries. These sense impressions are bound together into a cluster that defines the *bodily self*, so this is probably the first aspect of the self-concept to develop.

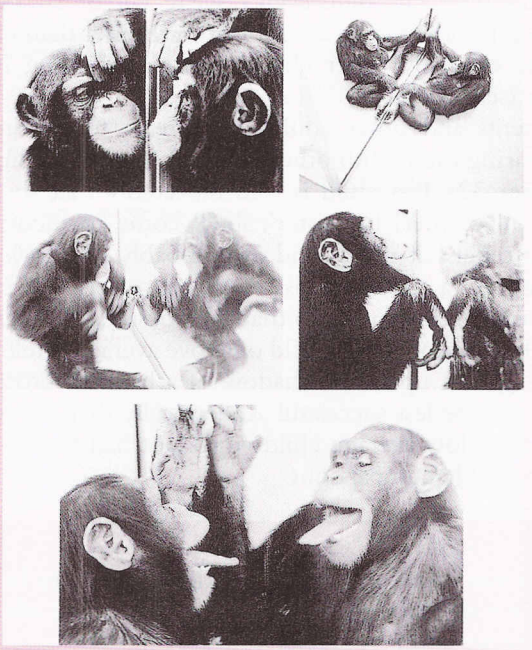
A baby acquiring its bodily self

Other aspects of the self-concept develop by degrees, but there seem to be fairly clearly defined stages of development. Young children may know their own names, and understand the limits of their own bodies, and yet be unable to think about themselves as coherent entities. So, self-awareness/self-consciousness develops very gradually.

According to Piaget, an awareness of self comes through the gradual process of *adaptation to the environment* (see Chapter 34). As the child explores objects and accommodates to them (thus developing new *sensorimotor schemas*), it simultaneously discovers aspects of its self. For example, trying to put a large block into its mouth and finding that it won't fit is a lesson in selfhood, as well as a lesson about the world of objects.

Self-recognition

One way in which the development of bodily self has been studied is through *self-recognition*, and this involves more than just a simple discrimination of bodily features. To determine that the person in a photograph or a film or reflected in a mirror is oneself, certain knowledge seems to be necessary:



- at least a rudimentary knowledge of oneself as continuous through time (necessary for recognising ourselves in photographs or movies) and space (necessary for recognising ourselves in mirrors), and
- knowledge of particular features (what we look like).

Although other kinds of self-recognition are possible (e.g. one's voice or feelings), only *visual* self-recognition has been studied extensively, both in humans and non-humans.

Many non-human animals (including fish, birds, chickens and elephants) react to their mirror-images as if they were other animals: they don't seem to recognise them as their own reflections at all. But self-recognition has been observed in the higher primates – chimpanzees and other great apes.

KEY STUDY 33.2 Mirror, mirror ... (Gallup, 1977)

- Gallup, working with preadolescent, wild-born chimps, placed a full-length mirror on the wall of each animal's cage. At first, they reacted as if other chimps had appeared – they threatened, vocalised, or made conciliatory gestures. But this quickly faded out, and by the end of three days had almost disappeared. They then used their images to explore themselves. For example, they'd pick up food and place it on their faces, which couldn't be seen without the mirrors (see photographs opposite).
- After ten days' exposure, each chimp was anaesthetised and a bright red spot was painted on the uppermost part of one eyebrow ridge, and a second spot on the top of the opposite ear, using an odourless, non-irritating dye.
- When the chimp had recovered from the anaesthetic, it was returned to its cage, from which the mirror had been removed, and it was observed to see how often it touched the marked parts of its body. The mirror was then replaced, and each chimp began to explore the marked spots around 25 times more often than it had done before.
- The procedure was repeated with chimps that had never seen themselves in the mirror, and they reacted to the mirror-image as if it were another chimp (they didn't touch the spots). So, the first group had apparently learned to recognise themselves.
- Lower primates (monkeys, gibbons, and baboons) are unable to learn to recognise their mirror-images.

Chimpanzees learn to use mirrors to explore parts of their bodies they cannot usually see

A number of researchers (e.g. Lewis & Brooks-Gunn, 1979) have used modified forms of Gallup's technique with 6–24-month-old children. The mother applies a dot of rouge to the child's nose (while pretending to wipe its face), and the child is observed to see how often it touches its nose. It's then placed in front of a mirror, and again the number of times it touches its nose is recorded. At about 18 months, there's a significant change. While touching the dot was never seen before 15 months, between 15 and 18 months, 5–25 per cent of infants touched it, and 75 per cent of the 18–24-month-olds did.

In order to use the mirror-image to touch the dot on its nose, the baby must also have built up a schema of how its face should look in the mirror before (otherwise, it wouldn't notice the discrepancy created by the dot). This doesn't develop before about 18 months. This is also about the time when, according to Piaget, *object permanence* is completed, so object permanence would seem to be a necessary condition for the development of self-recognition (see Chapter 34).

Interpreting Gallup's findings

It's generally agreed that passing the mirror test is strong evidence that a chimp has a self-concept, and that only chimps, orang-utans and humans consistently pass it.

However, Gallup (1998) infers much more than this. He claims that:

> ... not only are some animals aware of themselves but ... such self-awareness enables these animals to infer the mental states of others. In other words, species that pass the mirror test are also able to sympathise, empathise and attribute intent and emotions in others – abilities that some might consider the exclusive domain of humans.

He believes that self-awareness or self-consciousness is the expression of some underlying process that allows organisms to use their experience as a means of modelling the experience of others. The best support for this *mind-reading hypothesis* (MRH) comes from mirror studies involving human infants and young children (see above). Gallup's research also points to the *right prefrontal cortex* (see Chapter 4) as the brain area that mediates self-awareness and mental states (such as deception and gratitude) – and this is the brain region that grows most rapidly between 18 and 34 months.

As additional support for his MRH, Gallup cites studies by Povinelli and his colleagues involving chimps. These studies are often taken to show that chimps have a 'theory of mind' (see Chapter 40). Ironically, Povinelli (1998) himself disagrees with Gallup's MRH. While agreeing that passing the mirror test indicates that chimps possess a self-concept, he disagrees that this means that they also possess the deep psychological understanding of behaviour that seems so characteristic of humans.

If chimps *don't* genuinely reason about mental states, what can we say about their understanding of self based on the mirror test? Povinelli has tried to answer this by shifting his attention from chimps to two-, three-, and four-year-old children.

KEY STUDY 33.3 Stickers, lies and videotape (Povinelli, 1998)

- In a series of experiments, children were videotaped while they played an unusual game. The experimenter placed a large, brightly coloured sticker secretly on top of the child's head. Three minutes later, they were shown either (a) a live video image of themselves, or (b) a recording made several minutes earlier, which clearly depicted the experimenter placing the sticker on the child's head.
- Two- and three-year-olds responded very differently, depending on which video they saw. With the live image (equivalent to seeing themselves in a mirror), most reached up and removed the stickers from their heads. But with the recording, only about one third did so. However, this wasn't because they failed to notice the stickers (when the experimenter drew their attention to them and asked 'What is that?', most gave the correct answer).
- They also 'recognised' themselves in the recording – they all confidently responded with 'Me' and stated their name when asked 'Who is that?'. But this reaction didn't seem to go beyond a recognition of facial and bodily features. When asked 'Where is that sticker?', they often referred to the 'other' child (e.g. 'It's on her/his head'), as if they were trying to say 'Yes, that looks like me, but that's not *me* – she's not doing what I'm doing right now'. One three-year-old said 'It's Jennifer' (her name), then hurriedly added 'but why is she wearing my shirt?'
- By about four, a significant majority of the children began to pass the delayed self-recognition test. Most four- and five-year-olds confidently reached up to remove the stickers after watching the delayed video images of themselves. They no longer referred to 'him/her' or their proper names.

According to Povinelli, these results are consistent with the view that genuine *autobiographical memory* (AM) appears to emerge in children between three-and-a-half and four-and-a-half (not the two-year mark favoured by Gallup). AM implies understanding that memories constitute a genuine 'past' – a history of the self leading up to the here-and-now (see Chapter 17).

It also suggests that self-recognition in chimps – and human toddlers – is based on recognition of the self's *behaviour,* not the self's psychological states. When chimps and orang-utans see themselves in a mirror, Povinelli (1998) believes they:

> ... form an equivalence relation between the actions they see in the mirror and their own behaviour. Every time they move, the mirror image moves with them. They conclude that everything that is true for the mirror image is also true for their own bodies, and vice versa. Thus, these apes can pass the mirror test by correlating coloured marks on the mirror images with marks on their own bodies. But the ape does not conclude, 'That's me!'. Rather the animal concludes, 'That's the same as me!'

In short, chimps possess explicit mental representations of the positions and movements of their own bodies, which Povinelli calls the *kinaesthetic self-concept* (see Chapter 5).

Gallup's MRH relates to what Dunbar (2004) calls *second order intentionality* (the capacity to reflect on the contents of *someone else's mind*). His research suggests that humans are limited to *fifth order intentionality* ('I suppose [1] that you believe [2] that I want [3] you to think [4] that I intend [5] ...'). Chimps (and perhaps other great apes) may be capable of *second order,* and monkeys stop at *first order* (along with most mammals and birds). Dunbar believes that these capacities are a linear function of the relative size of the frontal lobe: a large neocortex in general, and frontal lobes in particular, is a 'primate speciality'. However, mind-reading *isn't* a specialised primate or even human capacity: there's only a *quantitative*

difference between species in the number of orders of intentionality they can travel.

Self-definition

Piaget, Mead, and many others have pointed to the importance of language in consolidating the early development of self-awareness, by providing labels which permit distinctions between self and not-self ('I', 'you', 'me', 'it'). The toddler can then use these labels to communicate notions of selfhood to others. One important kind of label is the child's *name*.

Names aren't usually chosen arbitrarily – either the parents particularly like the name, or they want to name the child after a relative or famous person. Names aren't neutral labels in terms of how people respond to them and what they associate with them.

Gwyneth Paltrow with baby Apple

Indeed, they can be used as the basis for *stereotyping* (see Chapter 22). Jahoda (1954) described the naming practices of the Ashanti tribe of West Africa. Children born on different days of the week are given names accordingly, because of the belief that they have different personalities. Police records showed that among juvenile delinquents, there was a very low percentage of boys born on Monday (believed to have quiet and calm personalities), but a very high rate of Wednesday-born boys (thought to be naturally aggressive).

ASK YOURSELF...

- How might the boys' names have contributed to these statistics?

These findings can be explained in terms of the *self-fulfilling prophecy*. It's reasonable to believe that these Ashanti boys were treated in a way consistent with the name given to them, and that, as a result, they 'became' what their name indicated they were 'really' like. In English-speaking countries, days of the week (e.g. Tuesday) and months of the year (April, May and June) are used as names, and they have associations which may influence others' reactions (for example, 'Monday's child is fair of face, Tuesday's child is full of grace ...').

When children refer to themselves as 'I' (or 'me') and others as 'you', they're having to reverse the labels that are normally used to refer to them by others ('you', 'he', 'she'). Also, of course, they hear others refer to themselves as 'I' and not as 'you', 'he', or 'she'. This is a problem of *shifting reference*. Despite this, most children don't invert 'I' and 'you'. However, two interesting exceptions are autistic and blind children, who often use 'I' for others and 'you' for self (see Chapter 40). This may be associated with the abnormal interactions and relationships these children experience which, in turn, would further support Cooley and Mead.

The psychological self

Maccoby (1980) asks what children mean when they refer to themselves as 'I' or 'me'. Are they referring to anything more than a physical entity enclosed by an envelope of skin?

KEY STUDY 33.4 There's more to children than meets the eye (Flavell *et al.*, 1978)

- Flavell *et al.* (1978) investigated development of the psychological self in two-and-a-half to five-year-olds.
- In one study, a doll was placed on the table in front of the child, and it was explained that dolls are like people in some ways – they have arms, legs, hands, and so on (which were pointed to). Then the child was asked how dolls are different from people, whether they know their names and think about things, and so on. Most children said a doll doesn't know its name and cannot think about things, but people can.
- They were then asked, 'Where is the part of you that knows your name and thinks about things?' and 'Where do you do your thinking and knowing?', and 14 out of 22 children gave fairly clear localisation for the thinking self, namely 'in their heads', while others found it very difficult. The experimenter then looked directly into the child's eyes and asked, 'Can I see you thinking in there?' Most children thought not.

These answers suggest that by three-and-a-half to four years, a child has a rudimentary concept of a private, thinking self that's not visible even to someone looking directly into its eyes. The child can distinguish this from the bodily self, which it knows is visible to others. In

other words, by about age four, children begin to develop a *theory of mind,* the awareness that they – and other people – have mental processes (e.g. Leekam, 1993; Shatz, 1994; Wellman, 1990). However, one group failing to develop a theory of mind is autistic children (see Chapter 40).

The categorical self

Age and *gender* are both parts of the central core of the self-image. They represent two of the categories regarding the self which are also used to perceive and interpret the behaviour of others.

Age is probably the first social category to be acquired by the child (and is so even before a concept of number develops). Lewis & Brooks-Gunn (1979) found that six- to 12-month-olds can distinguish between photographs, slides and papier-mâché heads of adults and babies. By 12 months, they prefer interacting with unfamiliar babies to unfamiliar adults. Also, as soon as they've acquired labels like 'mummy' and 'daddy' and 'baby', they almost never make age-related mistakes.

Before age seven, children tend to define the self in *physical* terms – hair colour, height, favourite activities and possessions. Inner, psychological experiences and characteristics aren't described as being distinct from overt behaviour and external, physical characteristics. During middle childhood through to adolescence, self-descriptions now include many more references to internal, psychological characteristics, such as competencies, knowledge, emotions, values and personality traits (Damon and Hart, 1988). However, Damon and Hart also report important cultural differences in how the self-concept develops (see Critical Discussion 33.2).

School highlights others' expectations about how the self should develop. It also provides a social context in which new goals are set and comparisons with others (peers) are prompted. This makes evaluation of the self all the more important (Durkin, 1995). This comparison becomes more important still during adolescence (see Chapter 37).

CHAPTER SUMMARY

- An important distinction is that between **consciousness** and self-**consciousness/awareness**. Self-awareness allows us to see ourselves as others see us.
- Our **self-concept** refers to our perception of our personality, and comprises the **self-image** (which includes **body image/bodily self**), **self-esteem**, and **ideal self.** It can also be defined in terms of a complex set of **self-schemata**, which themselves include an array of possible selves.
- A major theoretical approach to the self is **symbolic interactionism**, associated mainly with Mead, who was influenced by James's **'I'/'me' distinction** and by Cooley's theory of the **looking-glass self**.
- Mead denied that the self is mentalistic, seeing it as a **process of social interaction**. It develops through **role-taking**, in particular, taking the perspective of the '**generalised other**' in the context of the child's play.
- Based on Mead, many sociologists and social psychologists see **language** as fundamental to how the self is **constructed**. Our language provides stories or accounts of what being a person is like ('**discourses**'), which differ between cultures. The view of people as independent, self-contained individuals is a relatively recent invention of western, individualist cultures.
- Two major influences on the development of the self-concept are the **reaction of others** and **comparison with others**. Much of the relevant research is consistent with the theories of James, Cooley and Mead.
- The self-concept develops in fairly regular, predictable ways. During the first few months, the **existential self** emerges, but the **bodily self** is probably the first aspect of the self-concept to develop.
- The bodily self has been studied through (mainly visual) **self-recognition in mirrors**. Self-recognition appears at about 18 months in children, and is also found in chimps.
- While it's generally agreed that passing the mirror test implies a self-concept, this may be no more than a **kinaesthetic self-concept**, which doesn't involve an understanding of psychological states.
- **Self-definition** is related to the use of language, including the use of labels, such as names. By three-and-a-half to four, children seem to have a basic understanding of a **psychological self** (or '**theory of mind**').
- **Age** and **gender** are two basic features of the **categorical self**. The categorical self changes from being described in **physical** to more **psychological** terms during middle childhood through to adolescence.

Links with other topics/chapters

- '*Consciousness*' has several meanings and should be distinguished from 'self-consciousness'/'self-awareness' (Chapter 7).
- One account of how we get to know ourselves is *Bem's self-perception theory* (Chapters 23 and 24). Another, specifically concerned with our emotional experience, is *Schachter's cognitive labelling theory* (Chapter 10).
- The fact that non-humans are sentient raises fundamental *ethical* issues about using them in psychological (and medical) research. The possibility that certain non-human primates may also possess self-consciousness makes their use all the more controversial (Chapter 48).
- The bodily changes involved in *puberty* affect the *adolescent's body image,* which, in turn, affects the self-concept as a whole (Chapter 37).

- *Biological sex* is another fundamental aspect of body image. *Gender* is the social equivalent/social interpretation of sex, and our *gender/gender identity* is another part of the central core of our self-image (Chapter 36).
- *Ageing* involves an inevitable decline in the body's ability to function, as well as characteristic changes in physical appearance (Chapter 39).
- High but fragile and inflated self-esteem can help explain many cases of *aggression* and *violence* (Chapter 29).
- The self-consistency motive implies that self-esteem is threatened by inconsistency (Tesser, 2004). Festinger's *cognitive dissonance theory* has come to be interpreted in terms of threat to self-esteem (Chapter 24).
- Harré's analysis of the concept of self is made from the perspective of *discursive psychology,* which is a *social constructionist* approach (Chapter 2).
- The effect of threat to self on our view of others applies to groups (and not just other individuals). Adorno *et al.*'s *authoritarian personality* claims that *prejudice* and *discrimination* are functional – they can help conceal our own inadequacies (Chapter 25).

COGNITIVE DEVELOPMENT

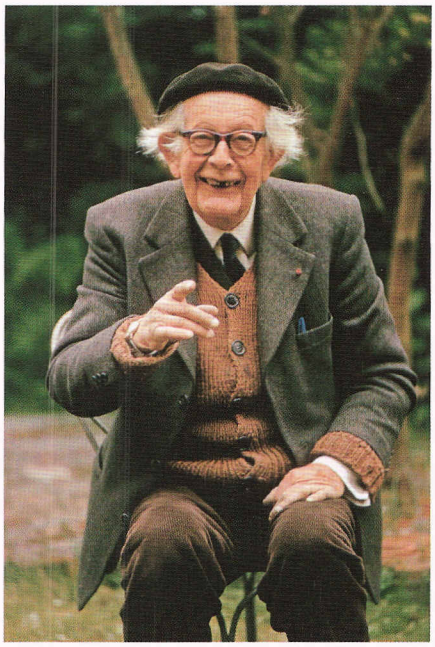
INTRODUCTION AND OVERVIEW

According to Meadows (1993, 1995), cognitive development is concerned with the study of 'the child as thinker'. However, different theoretical accounts of how the child's thinking develops rest on very different images of what the child is like:

- Piaget sees the child as an *organism adapting to its environment,* as well as a *scientist constructing its own understanding of the world*
- Vygotsky, in contrast with Piaget (and the information-processing approach), sees the child as a *participant in an interactive process,* by which socially and culturally determined knowledge and understanding gradually become *individualised*
- Bruner, like Vygotsky, emphasises the *social* aspects of the child's cognitive development
- Information-processing theorists see children, like adults, as *symbol manipulators.*

Some years ago, Piaget's theory was regarded as the major framework or paradigm within child development. Despite remaining a vital source of influence and inspiration, both in psychology and education, today there are hardly any 'orthodox' Piagetians left (Dasen, 1994). Many fundamental aspects of Piaget's theory have been challenged, and fewer and fewer developmental psychologists now subscribe to his or other 'hard' stage theories (Durkin, 1995). Nonetheless, Piaget's is still the most comprehensive account of how children come to understand the world (Schaffer, 2004). Arguably, however, it was a little too 'cold' – that is, concerned with purely *intellectual* functions that supposedly can be studied separately from socio-emotional functions. Vygotsky tried to redress the balance (Schaffer, 2004).

PIAGET'S THEORY: THE CHILD AS SCIENTIST



Rather than trying to explain individual differences (why some children are more intelligent than others: see Chapter 41), Piaget was interested in how intelligence itself changes as children grow. He called this *genetic epistemology.*

According to Piaget, cognitive development occurs through the interaction of innate capacities with environmental events, and progresses through a series of *hierarchical, qualitatively different, stages.*

- All children pass through the stages in the *same sequence* without skipping any or (except in the case of brain damage) regressing to earlier ones (they're *invariant*).
- The stages are also the *same for everyone* irrespective of culture (they're *universal*).
- Underlying the changes are certain *functional invariants,* fundamental aspects of the developmental process which remain the same and work in the same way through the various stages. The most important of these are *assimilation, accommodation,* and *equilibration.*
- The principal *cognitive structure* that changes is the *schema* (plural *schemas* or *schemata*).

Schemas (or schemata)

A *schema* (or *scheme*) is the basic building block or unit of intelligent behaviour. Piaget saw schemas as mental structures which organise past experiences and provide a way of understanding future experiences. For Bee (2000), they're not so much categories as the *action of categorising* in some particular way. Life begins with simple schemas, which are largely confined to inbuilt reflexes (such as sucking and grasping). These operate independently of other reflexes, and are activated only when certain objects are present. As we grow, so our schemas become increasingly complex.

Jean Piaget (1896–1980)

Assimilation, accommodation and equilibration

Assimilation is the process by which we incorporate new information into existing schemas. For example, babies will reflexively suck a nipple and other objects, such as a finger. To learn to suck from a bottle or drink from a cup, the initial sucking reflex must be modified through *accommodation.*

When a child can deal with most, if not all, new experiences by assimilating them, it's in a state of *equilibrium.* This is brought about by *equilibration,* the process of seeking 'mental balance'. But if existing schemas are inadequate to cope with new situations, cognitive *disequilibrium* occurs. To restore equilibrium, the existing schema must be 'stretched' in order to take in (or 'accommodate') new information. The necessary and complementary processes of assimilation and accommodation constitute the fundamental process of *adaptation* (see Figure 34.1).

Stages of cognitive development

Each of Piaget's four stages represents a stage in the development of intelligence (hence *sensorimotor intelligence, pre-operational intelligence,* and so on), and is a way of summarising the various schemas a child has at a

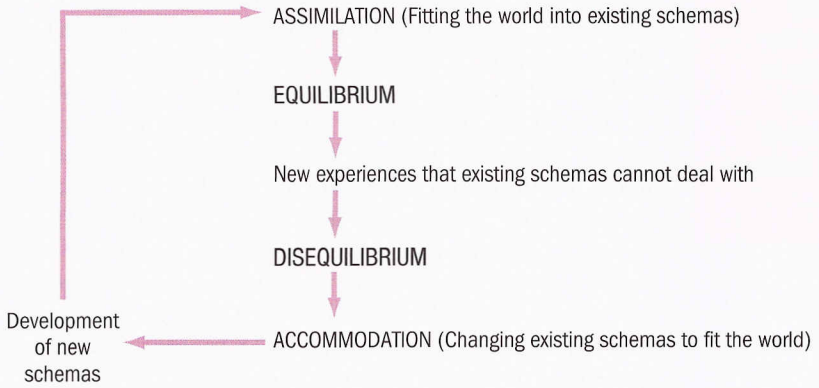


Figure 34.1 Relationship between assimilation, equilibrium, disequilibrium and accommodation in the development of schemas

particular time. The ages shown in Table 34.1 are approximate, because children move through the stages at different rates due to differences in both the environment and their biological maturation. Children also pass through transitional periods, in which their thinking is a mixture of two stages.

Table 34.1 Piaget's four stages of cognitive development

Stage	Approximate age
Sensorimotor	0–2 years
Pre-operational	2–7 years
Concrete operational	7–11 years
Formal operational	11 years onwards

The sensorimotor stage

This lasts for approximately the first two years of life. Infants learn about the world primarily through their senses ('sensori-'), and by doing ('motor'). Based on observations of his own children, Piaget (1952) divided the sensorimotor stage into six substages.

Box 34.1 Reflexes: the six sub-stages of the sensorimotor stage

- **Exercising reflexes (birth to 1 month):** Reflexes are practised until they function smoothly. Infants have no intentionality, and no understanding of an object.
- **Primary circular reactions (1–4 months):** Reflexes are extended to new objects, and infants coordinate simple schemas (such as grasping and looking). Behaviours causing specific events are repeated. Infants look briefly at where a disappearing object was last seen.
- **Secondary circular reactions (4–10 months):** All the senses become coordinated, and the infant can anticipate events and results of actions. A partially hidden object can be found.
- **The coordination of secondary circular reactions (10–12 months):** Infants represent objects in their minds, and demonstrate the beginning of symbolic behaviour and memory. A goal can be decided and then acted on. A completely hidden object can be found.
- **Tertiary circular reactions (12–18 months):** Infants search for environmental novelty and use several interchangeable schemas to achieve goals. Experiments are conducted to see what will happen. An object hidden under one of several covers can be found.
- **Invention of new means through mental combinations (18–24 months):** Infants think about a problem before acting, and thoughts begin to dominate actions. Objects can be manipulated mentally to reach goals. An object placed in a container and then hidden can be found.

(Based on Tomlinson-Keasey, 1985)

Object permanence

Frequent interaction with objects ultimately leads to the development of *object permanence.* As Box 34.1 shows, in the second substage an infant will look where an object disappears for a few moments, but won't search for it. If the object doesn't reappear, the infant apparently loses interest. Piaget called this *passive exploration,* because the infant expects the object to reappear but doesn't actively search for it ('out of sight' is 'out of mind').

In the third substage, an infant will reach for a partially hidden object, suggesting that it realises that the rest of it is attached to the visible part. But if the object is completely hidden, infants make no attempt to retrieve it.

CASE STUDY 34.1 An illustration of lack of object permanence (Piaget, 1963)

At 0,7 (28) [7 months, 28 days] Jacqueline tries to grasp a celluloid duck on top of her quilt. She almost catches it, shakes herself and the duck slides down beside her. It falls very close to her hand but behind a fold in the sheet. Jacqueline's eyes have followed the movement, she has even followed it with her outstretched hand. But as soon as the duck has disappeared – nothing more! It does not occur to her to search behind the fold of the sheet, which

would be very easy to do (she twists it mechanically without searching at all) ... I try showing it to her a few times. Each time she tries to grasp it, but when she is about to touch it I replace it very obviously under the sheet. Jacqueline immediately withdraws her hand and gives up ... Everything occurs as though the child believed that the object is alternately made and unmade ....

In the fourth substage, a hidden object will be searched for ('out of sight' is no longer 'out of mind'), but the infant will persist in looking for it where it was last hidden, even when it's hidden somewhere else (see Figure 34.2).

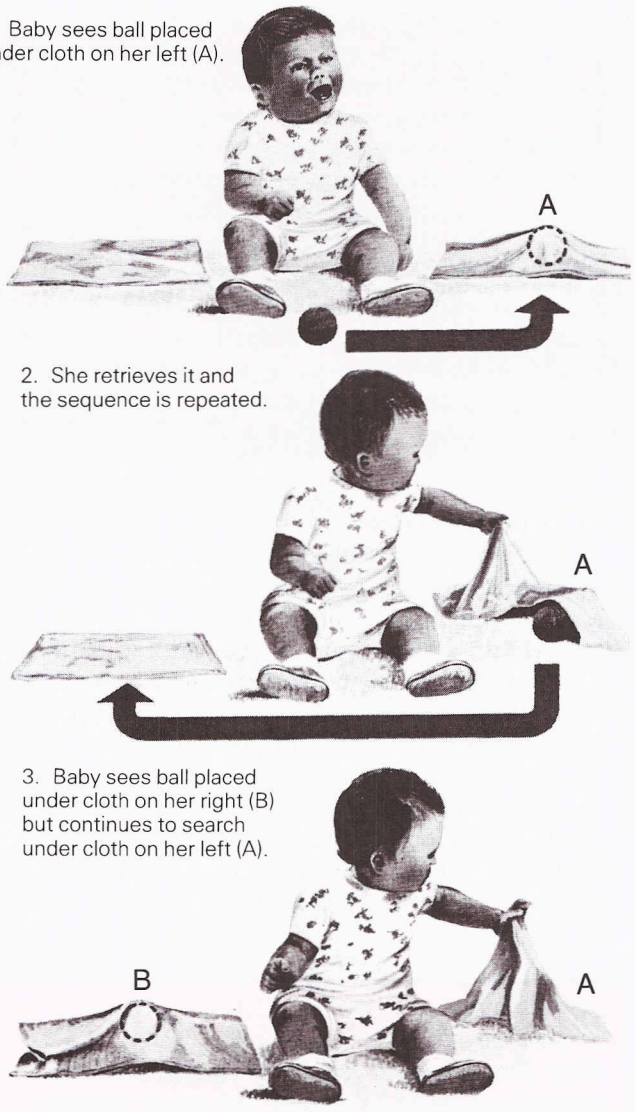

Figure 34.2 Piaget's demonstration of the limited object permanence of babies between eight and twelve months. They can retrieve a hidden object only from its original hiding place, not where it was last hidden. Not until about twelve months will they search under the cushion where they last saw the object hidden; they can do this even when three or four cushions are used. (Others have suggested that this ability appears as early as nine months.) (from Barnes-Gutteridge, 1974)

While after 12 months infants will look for an object where they last saw it hidden, object permanence isn't yet fully developed. Suppose an infant sees an object placed in a matchbox, which is then put under a pillow. When it's not looking, the object is removed from the matchbox and left under the pillow. If the matchbox is given to the infant, it will open it expecting to find the object. On not finding it, the infant won't look under the pillow. This is because it cannot take into account the possibility that something it's not actually seen might have happened (*failure to infer invisible displacements*). Once the infant can infer invisible displacements (after 18 months), the development of object permanence is complete.

Box 34.2 The general symbolic function

- Other cognitive structures that have developed by the end of the sensorimotor stage include *self-recognition* (see Chapter 33), and *symbolic thought* (such as *language*).
- Two other manifestations of the *general symbolic function* are *deferred imitation* and *representational* (or *make-believe*) *play*.
- Deferred imitation is the ability to imitate or reproduce something that's been perceived but is no longer present (Meltzoff & Moore, 1983).
- Representational play involves using one object as though it were another. Like deferred imitation, this ability depends on the infant's growing ability to form mental images of things and people in their absence (to *remember*).

The pre-operational stage

Probably the main difference between this and the sensorimotor stage is the continued development and use of internal images (or '*interiorised' schemas*), symbols and language, especially important for the child's developing sense of self-awareness (see Chapter 33). However, the child tends to be influenced by how things *look*, rather than by logical principles or operations (hence the term 'pre-operational').

Piaget subdivided the stage into the *pre-conceptual* (ages 2–4) and the *intuitive substages* (ages 4–7). The *absolute* nature of the pre-conceptual child's thinking makes relative terms such as 'bigger' or 'stronger' difficult to understand (things tend to be 'biggest' or just 'big'). The intuitive child can use relative terms, but its ability to think logically is still limited.

Seriation and artificialism

In *seriation*, the pre-conceptual child has difficulty arranging objects on the basis of a particular dimension, such as increasing height (Piaget & Szeminska, 1952). *Artificialism* is the belief that natural features have been designed and constructed by people. For example, the question 'Why is the sky blue?' might produce the answer 'Somebody painted it'.

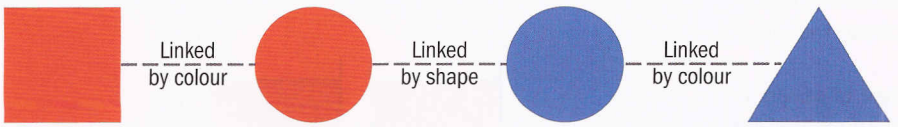

Figure 34.3 Simple example of syncretic thought

Syncretic thought, transductive reasoning, and animism

Syncretic thought is the tendency to link together any neighbouring objects or events on the basis of what individual instances have in common. For example, if a three-year-old is given a box of wooden shapes of different colours and asked to pick out four that are alike, the child might pick the shapes shown in Figure 34.3. Here, the characteristic the child focuses on changes with each second shape that's chosen: a red square is followed by a red circle, which is followed by a blue circle, which is followed by a blue triangle. There's no one characteristic that all four have in common. A five-year-old would be able to select four of the same shape, or four of the same colour, and say what they have in common.

Transductive reasoning involves drawing an inference about the relationship between two things based on a single shared attribute. If both cats and dogs have four legs, then cats must be dogs. This sort of reasoning can lead to *animism,* the belief that inanimate objects are alive.

Box 34.3 Examples of children's animism during the pre-operational stage (from Piaget, 1973)

Cli (three years, nine months) speaking of a motor in a garage: 'The motor's gone to bye-byes. It doesn't go out because of the rain ...'

Nel (two years, nine months) seeing a hollow chestnut tree: 'Didn't it cry when the hole was made?' To a stone: 'Don't touch my garden! ... My garden would cry.' Nel, after throwing a stone onto a sloping bank, watching the stone rolling down said: 'Look at the stone. It's afraid of the grass.'

Nel scratched herself against a wall. Looking at her hand: 'Who made that mark? – It hurts where the wall hit me.'

Dar (one year, eight months/two years, five months) bringing his toy motor to the window: 'Motor see the snow.' Dar stood up in bed, crying and calling out: 'The mummies (the ladies) all on the ground, hurt!' Dar was watching the grey clouds. He was told that it was going to rain. 'Oh, look at the wind! Naughty wind, smack wind.' ... On a morning in winter when the sun shone into the room: 'Oh, good! The sun's come to make the radiator warm.'

ASK YOURSELF...

- Can you think of any examples of adults displaying animistic thinking?
- Do you ever think this way yourself?

Centration

Centration involves focusing on only a single perceptual quality at a time. A pre-conceptual child asked to divide apples into 'big and red' ones and 'small and green' ones will either put all the red (or green) apples together irrespective of their size, or all the big (or small) apples together irrespective of their colour. Until the child can *decentre,* it will be unable to classify things logically or systematically. Centration is also associated with the *inability* to conserve (see below).

ASK YOURSELF...

- How is centration illustrated by syncretic thought (see above)?

Egocentrism

According to Piaget, pre-operational children are *egocentric,* that is, they see the world from their own standpoint and cannot appreciate that other people might see things differently. They cannot put themselves 'in other people's shoes' to realise that other people don't know or perceive everything they themselves do. Consider the following example (Phillips, 1969) of a conversation between an experimenter and a four-year-old boy:

Experimenter:	'Do you have a brother?'
Child:	'Yes.'
Experimenter:	'What's his name?'
Child:	'Jim.'
Experimenter:	'Does Jim have a brother?'
Child:	'No.'

KEY STUDY 34.1 The 'Swiss mountain scene' test of egocentrism (Piaget & Inhelder, 1956)

- The three papier-mâché model mountains shown in Figure 34.4 are of different colours. One has snow on the top, one a house, and one a red cross.
- The child walks round and explores the model, and then sits on one side while a doll is placed at some different location. The child is shown 10 pictures of different views of the model and asked to choose the one that represents how the doll sees it.
- Four-year-olds were completely unaware of perspectives other than their own, and always chose a picture which matched *their* view of the model. Six-year-olds showed some awareness, but often chose the wrong picture. Only

seven- and eight-year-olds consistently chose the picture that represented *the doll's* view.

- According to Piaget, children below the age of seven are bound by the *egocentric illusion*. They fail to understand that what they see is *relative to their own position*, and instead take it to represent 'the world as it really is'.

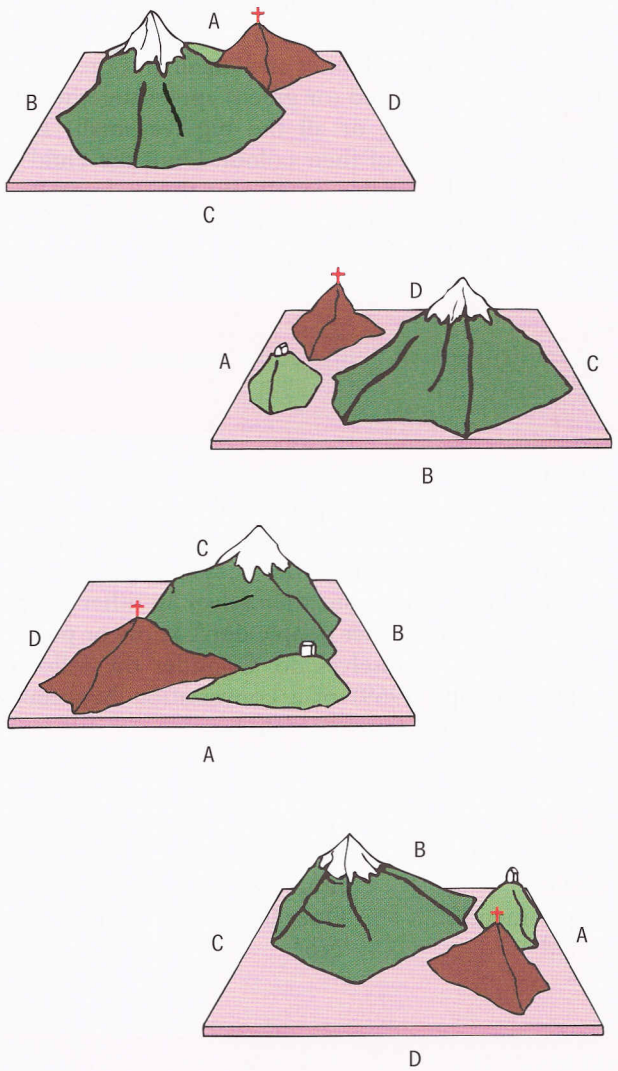

Figure 34.4 Piaget and Inhelder's three-mountain scene, seen from four different sides (from Smith & Cowie, 1988)

Conservation

Conservation is the understanding that any quantity (such as number, liquid quantity, length, or substance) remains the same despite physical changes in the arrangement of objects. Piaget believed that pre-operational children cannot conserve because their thinking is dominated by the *perceptual* nature of objects (their 'appearance').

The inability to conserve is another example of centration. With liquid quantity, for example, the child centres on just one dimension of the beaker, usually its height, and fails to take width into account (see Figure 34.5).

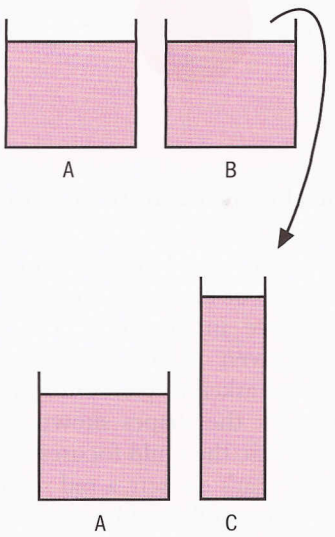

Figure 34.5 The conservation of liquid quantity. Although the child agrees that there's the same amount of liquid in A and B, when the contents of B are poured into C, the appearance of C sways the child's judgement so that C is now judged to contain more liquid than A ('it looks more' or 'it's taller'). Although the child has seen the liquid poured from B into C and agrees that none has been spilled or added in the process (what Piaget calls 'identity'), the appearance of the higher level of liquid in the taller, thinner beaker C is compelling

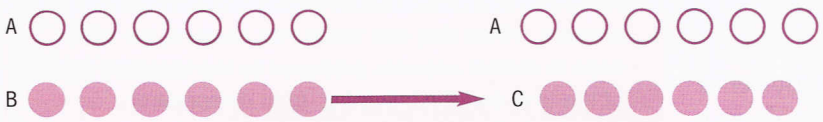
Only in the concrete operational stage do children understand that 'getting taller' and 'getting narrower' tend to cancel each other out (*compensation*). If the contents of the taller beaker are poured back into the shorter one, the child will again say that the two shorter beakers contain the same amount. But it cannot perform this operation mentally and so lacks *reversibility* (understanding that what can be done can be undone without any gain or loss). These same limitations apply to other forms of conservation, such as number, and substance/quantity (see Figures 34.6 and 34.7).

The concrete operational stage

The child is now capable of performing logical operations, but only in the presence of actual objects. S/he can conserve, and shows reversibility and more logical classification.

Further examples of the child's ability to decentre include its appreciation that objects can belong to more than one class (as in the case of Andrew being Bob's brother *and* Charlie's best friend). There's also a significant *decline* in egocentrism (and the growing *relativism* of the child's viewpoint), plus the onset of seriation and reciprocity of relationships (such as knowing that adding one to three produces the same amount as taking one from five).



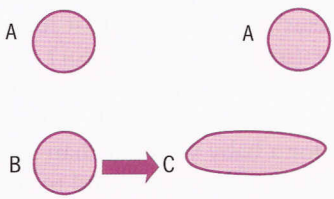


Figure 34.6 Number conservation using counters. Two rows of counters are put in a one-to-one correspondence and then one row is pushed together. The pre-operational child usually thinks there are more counters in A than in C because A is 'longer', despite being able to count correctly and agreeing that A and B have equal numbers

Figure 34.7 Substance or quantity conservation using plasticine. Two equal-sized balls of plasticine are used. B is rolled into a sausage shape (C); the pre-operational child typically thinks there's more plasticine in C than A, having originally agreed that A and B have the same amount

One remaining problem for the concrete operational child is *transitivity tasks.* For example, if told that 'Alan is taller than Bob, and Bob is taller than Charlie' and asked whether Alan or Charlie is taller, children under eleven cannot solve this problem entirely in their heads. They can usually only solve it using real (or concrete) objects (such as dolls).

Box 34.4 Horizontal and vertical décalage

- Some types of conservation are mastered before others, and their order tends to be invariant.
- *Liquid quantity* is mastered by age 6–7, *substance/quantity* and *length* by 7–8, *weight* by 8–10, and *volume* by 11–12.
- This step-by-step acquisition of new operations is called *décalage* (displacement or 'slips in level of performance').
- In conservation, décalage is *horizontal* because there are inconsistencies *within* the same kind of ability or operation (a seven-year-old child can conserve number but not weight, for example). *Vertical* décalage refers to inconsistencies *between* different abilities or operations (a child may have mastered all kinds of classification, but not all kinds of conservation).

The formal operational stage

While the concrete operational child is still concerned with manipulating things (even if this is done mentally), the formal operational thinker can manipulate *ideas* or *propositions* and can reason solely on the basis of verbal statements ('first order' and 'second order' operations respectively). 'Formal' refers to the ability to follow the form of an argument without reference to its particular content. In transitivity problems, for example, 'If A is taller than B, and B is taller than C, then A is taller than C', is a form of argument whose conclusion is logically true, regardless of what A, B and C might refer to.

Formal operational thinkers can also think *hypothetically,* that is, about what *could be* as well as what *actually is.* For example, asked what it would be like if people had tails, they might say 'Dogs would know when you were happy' or 'Lovers could hold their tails in secret under the table'. Concrete operational thinkers might tell you 'not to be so silly', or say where on the body the tail might be, showing their dependence on what they've actually seen (Dworetzky, 1981). This ability to imagine and discuss things that have never been encountered is evidence of the continued decentration that occurs beyond concrete operations.

Formal operational thinkers also display *hypothetico-deductive reasoning,* as demonstrated in a series of tasks devised by Inhelder & Piaget, 1958.

KEY STUDY 34.2 A demonstration of formal operational thinking (Inhelder & Piaget, 1958)

- Inhelder and Piaget gave adolescents five containers filled with clear liquid. Four were 'test chemicals' and one an 'indicator'. When the correct combination of one or more test chemicals was added to the indicator, it turned yellow. The problem was to find this combination.
- *Pre-operational children* simply mixed the chemicals randomly, and *concrete operational* children, although more systematic, generally failed to test all possible combinations.
- Only *formal operational* thinkers considered all alternatives and systematically varied one factor at a time. Also, they often wrote down all the results and tried to draw general conclusions about each chemical.

An evaluation of Piaget's theory

As we noted in the *Introduction and overview* Piaget's theory has had an enormous impact on our understanding of cognitive development. However, as Flavell (1982), and others (e.g. Siegal, 2003) have remarked:

> Like all theories of great reach and significance ... it has problems that gradually come to light as years and years of thinking and research get done on it. Thus, some of us now think that the theory may in varying degrees be unclear, incorrect and incomplete.

Object permanence

Piaget's claims about the sensorimotor stage have been criticised in both general and specific terms. Bower & Wishart (1972), for example, found that how an object is made to disappear influences the infant's response. If the infant is looking at an object and reaching for it and the lights are turned off, it will continue to search for up to one-and-a-half minutes (as observed using infrared cameras). This suggests that it *does* remember the object is there (so, 'out of sight' *isn't* 'out of mind'). Baillargeon (1987) has shown that object permanence can occur as early as three-and-a-half months, and that it isn't necessary for a baby younger than six months to see the whole object in order to respond to it.

Centration

One way to study centration (and classification) is through *class inclusion tasks.* If a pre-operational child is presented with several wooden beads, mostly brown but a few white, and asked 'Are they all wooden?', the child will respond correctly. If asked 'Are there more brown or more white beads?', the child will again respond correctly. But if asked 'Are there more brown beads or more beads?', the child will say there are more brown beads.

ASK YOURSELF...

- Why do you think they say there are more brown beads?

The brown beads are more numerous than the white, and can be perceived in a more immediate and direct way than the wooden beads as a whole (despite the first question being answered correctly). For Piaget, the child fails to understand the relationship between the whole (the *superordinate* class of wooden beads) and the parts (the *subordinate* classes of brown and white beads). This is another example of the inability to decentre. However, Donaldson (1978) has asked if the difficulty the child experiences is to do with what's expected of it and how the task is presented.

KEY STUDY 34.3 Let sleeping cows lie

- Donaldson (1978) describes a study with six-year-olds using four toy cows, three black and one white. The cows were laid on their sides and the children told they were 'sleeping'. Of those asked 'Are there more black cows or more cows?', 25 per cent answered correctly. But of those asked 'Are there more black cows or more sleeping cows?', 48 per cent answered correctly.
- Chapman & McBride (1992) conducted a similar study with four- to ten-year-olds involving sleeping horses. Although they replicated the results reported by Donaldson, most children couldn't effectively justify their answers. When this was taken into account, the difference in correct answers produced by the standard form of the task and the 'sleeping' form disappeared.
- In both studies, a majority of children still fail even under conditions where task demands are reduced. This suggests a deep *conceptual* difficulty, as well as a linguistic one (Siegal, 2003).

- According to Gelman (1978), the word 'more' has a different meaning for children and adults. Adults use 'more' to mean 'containing a greater number'. But for children 'more' refers to the general concept of larger, longer, occupying more space, and so on.

Egocentrism

Gelman (1979) has shown that four-year-olds adjust their explanations of things to make them clearer to a blindfold listener. This isn't what we'd expect if, as Piaget claims, children of this age are egocentric. Nor would we expect four-year-olds to use simpler forms of speech when talking to two-year-olds (Gelman, 1979) or choose appropriate birthday presents for their mothers (Marvin, 1975, in Morris, 1988).

Critics of the 'Swiss mountain scene' test (Key Study 34.1) see it as an unusually difficult way of presenting a problem to a young child. Borke (1975) and Hughes (cited in Donaldson, 1978) have shown that when the task is presented in a meaningful context (making what Donaldson calls 'human sense'), even three-and-a-half-year olds can appreciate the world as another person sees it. These are all examples of *perspective-taking.* According to Siegal (2003):

> ... A reasonable conclusion is that young children are not egocentric all of the time, but their perspective-taking skills clearly improve during childhood ...

Box 34.5 Perspective-taking, false beliefs and theory of mind

- According to Flavell *et al.* (1990), there are two levels of perspective-taking (PT) ability:
  - (a) *level 1* (two- to three-year-olds) – the child knows that some other person experiences something differently (*perceptual* PT)
  - (b) *level 2* (four- to five-year-olds) – the child develops a whole series of complex rules for figuring out precisely what the other person sees or experiences (*affective* and *cognitive* PT).
- In a study of children's ability to distinguish between appearance and reality, Flavell (1986) showed children a sponge painted to look like a rock. They were asked what it looked like and what it 'really' was. Three-year-olds said either that it looked like a sponge and was a sponge, or that it looked like a rock and was a rock. However, four- to five-year-olds could say that it looked like a rock but was in fact a sponge.
- Gopnik & Astington (1988) allowed children to *feel* the sponge before asking them the questions used in Flavell's study. The children were then told: 'Your friend John hasn't touched this, he hasn't squeezed it. If John just sees it over here like this, what will he think it is? Will he think it's a rock or a sponge?'

ASK YOURSELF...

- How do you think the three-year-olds answered?
- How do you think the four- to five-year-olds answered?

- Typically, three-year-olds said that John would think it was a sponge (which it is), while four- to five-year-olds said he'd think it was a rock (because he hadn't had the opportunity of touching/squeezing it). In other words, the older children were attributing John with a *false belief*, which they could do only by taking John's perspective.
- Evidence like this has led several theorists (e.g. Gopnik & Wellman, 1994) to propose that four- to five-year-olds have developed a quite sophisticated *theory of mind* (Premack & Woodruff, 1978). This refers to the understanding that people (and not objects) have desires, beliefs and other mental states, some of which (such as beliefs) can be false (*cognitive* PT). The older children in Gopnick and Astington's study understood that John wouldn't know something which *they did*.

Conservation

The ability to conserve also seems to occur earlier than Piaget believed. Rose & Blank (1974) showed that when the *pre-transformation question* (the question asked before one row of counters, say, is rearranged) was dropped, six-year-olds often succeeded on the number conservation task. Importantly, they made fewer errors on the standard version of the task when tested a week later. These findings were replicated by Samuel & Bryant (1984) using conservation of number, liquid quantity and substance.

According to Donaldson (1978), the standard version of the task unwittingly 'forces' children to produce the wrong answer against their better judgement, by the mere fact that the same question is asked twice, before and after the transformation. Hence, children believe they're expected to give a different answer on the second question. On this explanation, *contextual cues* may override purely linguistic ones. Children may think the experimenter has rejected their first answer, so they feel they're required to give a *different* answer on the second question in order to please the adult questioner. This is the problem of a *clash of conversational worlds* between child and adult (Siegal, 2003).

Bruner (1966) argues that children's attention is so captured by the transformed state that they disregard the pre-transformed state and fail to attend to it when asked the second question.

ASK YOURSELF...

- Apart from dropping the pre-transformation question, how else might conservation tasks be modified in order to prevent children from being distracted in this way?

Children can be asked to *predict* the outcome, without actually witnessing it. Under these conditions, those who'd normally 'fail' are more likely to give the correct answer (Siegal, 2003).

According to Piaget, it shouldn't matter *who*, in the case of number conservation, rearranges the counters/Smarties or how this happens. Yet when 'Naughty Teddy', a glove puppet, causes the transformation 'accidentally', pre-operational children can conserve number and length (McGarrigle & Donaldson, 1974; Light *et al.*, 1979). This also applies when the transformation is made by a person other than the experimenter (Hargreaves *et al.*, 1982; Light, 1986).

While Piaget's original procedure might convey the implicit message 'take note of the transformation because it's relevant', studies using *accidental transformations* (such as the 'Naughty Teddy' experiment) might convey the message 'ignore the transformation, it makes no difference'. The standard Piagetian task involves an *irrelevant perceptual change* (nothing is added or taken away). But where some *actual change* occurs, children tested under the accidental/incidental transformation condition should do *worse* than those tested in the standard way (due to the implicit message to ignore the transformation). This prediction has been supported in several studies (Light & Gilmour, 1983; Moore & Frye, 1986).

Cross-cultural tests of the stages

According to Schaffer (2004), Piaget's account gives the impression that the stages are an inevitable consequence of being human, and that external influences stemming from the social environment play no part. What evidence is there to support this?

The few cross-cultural studies of the sensorimotor stage have shown the substages to be universal. Overall, it seems that ecological or cultural factors *don't* influence the sequence of stages, but *do* affect the rate at which they're attained (Segall *et al.*, 1999).

CROSS-CULTURAL STUDY 34.1

Cultural influences on conservation and spatial relationships (Dasen, 1994)

- Dasen cites studies he conducted in remote parts of the central Australian desert with 8–14-year-old Aborigines. He gave them *conservation*-of-liquid, weight, and volume tasks, plus a task that tested understanding of *spatial relationships*. This involved either:
  (a) two landscape models, one of which could be turned round through 180° – the participants had to locate an object (doll or sheep) on one model and then find the same location on the second model, or
  (b) a bottle was half-filled with water, then tilted into various positions, with a screen hiding the water level – participants were shown outline drawings of the bottle and they had to draw in the water level.
- On *conservation* tasks, the same shift from pre-operational to concrete operational thought was found as with Swiss children – but it took place between 10–13 years of age (instead of 5–7). A fairly large proportion of adolescents and adults also gave non-conservation answers.

- On the *spatial* tasks, again there was the same shift from pre- to concrete operational thought as for Swiss children, but they found the spatial task *easier* than the conservation tasks. In other words, operational thinking develops earlier in the spatial domain, the *reverse* of what's found for Swiss children.
- According to Dasen, this makes good sense in terms of Aboriginal culture, where things *aren't quantified*. Water is vital for survival, but the exact quantity matters little. Counting things is unusual, and number words only go up to five (after which everything is 'many'). By contrast, finding one's way around is crucial: water-holes must be found at the end of each journey and family members meet up at the end of the day after having split up in order to search for water. The acquisition of a vast array of spatial knowledge is helped by the mythology, such as the 'dream time' stories that attribute a meaning to each feature of the landscape and to routes travelled by ancestral spirits.

Conservation experiments have also been conducted with Eskimo, African (Senegal and Rwande), Hong Kong and Papua New Guinea samples. Consistent with Dasen's findings, children from non-western cultures often show a considerable lag in acquiring operational thought. But this applies mainly to those having minimal contact with white culture. Where Aborigines, for example, live in white communities and attend school there, they perform at a similar level to whites. Even where there's a lag in development compared with whites, the stages still appear in the same order. So (as with the sensorimotor substages):

> ... Cultural factors ... can affect *rate* of attainment; they do not alter developmental *sequence* ... (Schaffer, 2004)

As Dasen (1994) puts it:

> The deep structures, the basic cognitive processes, are indeed universal, while at the surface level, the way these basic processes are brought to bear on specific contents, in specific contexts, is influenced by culture. Universality and cultural diversity are not opposites, but are complementary aspects of all human behaviour and development.

Dasen has argued that only one-third of adolescents and adults actually attain formal operations, and that in some cultures it's not the typical mode of thought. However, Shea (1985) argues that it would be premature to conclude that formal operations don't 'exist' in certain societies based on the results of a few Piagetian tasks. Highly abstract thinking of some kind can often be found in traditional court cases (Jahoda, 1980), and land disputes (Hutchins, 1980) – even if they're not strictly 'formal'. According to Segall *et al.* (1999), it might be more accurate to argue that formal operational thinking 'in effect, scientific reasoning – is not what is valued in all cultures'.

The role of social factors in cognitive development

Meadows (1995) maintains that Piaget implicitly saw children as largely independent and isolated in their construction of knowledge and understanding of the physical world (children as scientists). This excluded the contribution of other people to children's cognitive development. The social nature of knowledge and thought is a basic proposition of Vygotsky's theory (see below). According to Vygotsky (1987):

> The child [in Piaget's theory] is not seen as part of the social whole, as a subject of social relationships. He is not seen as a being who participates in the societal life of the social whole to which he belongs from the outset. The social is viewed as something standing outside the child.

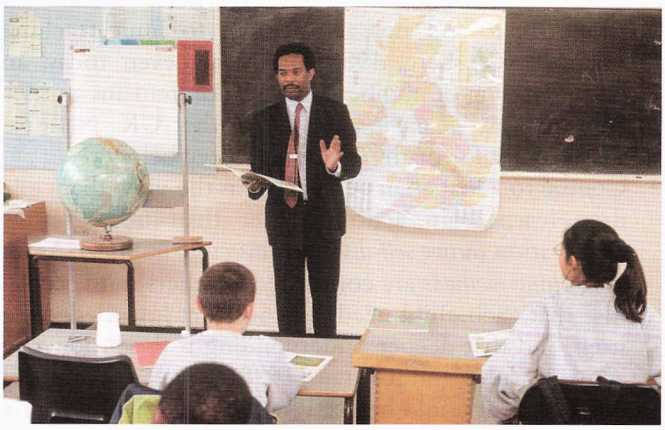
(We should note that one of the implications of Piaget's theory for education is that teachers should encourage *children learning from each other:* see Box 34.6.)

Despite all these (and other) criticisms, Siegal (2003) believes that:

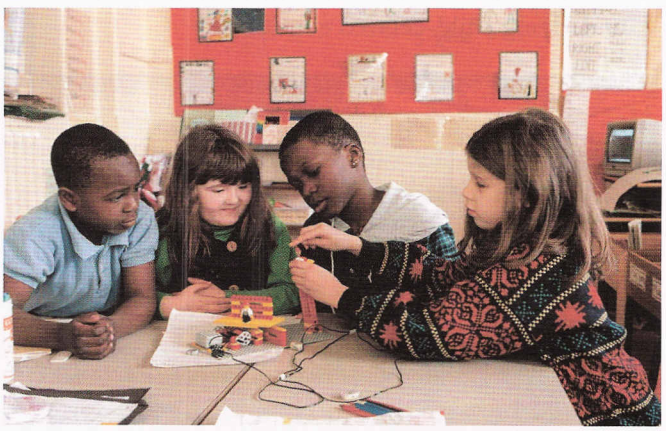
> ... Piaget's intriguing observations opened up many fruitful lines of enquiry and ... while many of his interpretations have by and large been modified or superseded, he set the agenda for a vast body of productive research in the twentieth and twenty-first centuries.

CRITICAL DISCUSSION 34.1 Does development really take place in stages?

- According to Flavell *et al.* (1993), there are three criteria for distinguishing a stage model.
  - (i) *Qualitative change:* at certain points in development, thought and behaviour undergo change that's not just a matter of doing something faster or with more precision. It's about doing it *differently,* such as adopting another *kind* of mental strategy.
  - (ii) *Abruptness of change:* a stage model portrays development as more of a staircase than an incline.
  - (iii) *Across-the-board change:* change occurs simultaneously in a wide range of functions (for example, a new stage in reasoning affects *all* aspects of problem-solving). This is known as *domain-general* change.



ASK YOURSELF...



- From what you know now of Piaget's theory and evaluations of it, do you consider that a domain-general (stage) approach is the most accurate/valid way of depicting children's cognitive development?

- Increasingly, psychologists in recent years have come to see development as more *complex, uneven* and *gradual* than it's described by stage models such as Piaget's. Instead, they argue that development is more accurately described as *domain-specific*. For instance, the example of egocentrism and PT (see Box 34.5) applies to other areas. As Schaffer (2004) puts it:

  > *... Development rarely assumes the stepwise form that this model suggests ... closer inspection reveals continuities which a theory based on periodically occurring qualitative shifts would not expect ... Piaget's domain-general view needs to be replaced by a domain-specific view ... development frequently occurs at different tempos and in different ways across various functions which Piaget had originally put all under one umbrella.*

- The way in which researchers such as Piaget (and Kohlberg: see Chapter 35) try to determine a child's developmental stage is to focus on *what individuals can do strictly on their own*. This reflects the implicit view of the individual as *self-regulating* and *independent* (Moghaddam, 2002), a view most clearly and vigorously rejected by Vygotsky (see below).

In the traditional classroom (top), the teacher is at the centre of the learning process imparting ready-made ('academic'/'school') knowledge. By contrast, in the Piagetian classroom (bottom), the child actively discovers knowledge for him/herself, often through interaction with other children in small groups

Applying Piaget's theory to education

Although Piaget wrote very little about the educational implications of his developmental theory (Davis, 2003), it has three main implications for education (Brainerd, 1983): the concept of *readiness,* the *curriculum* (what should be taught) and *teaching methods* (how the curriculum should be taught).

- *Readiness* relates to limits set on learning by a child's current stage of development (see Box 34.6). According to Schaffer (2004), Piaget's most relevant contribution to education (especially the teaching of maths and science: see below) is the recognition that careful thought must be given to the individual child's capacity for handling particular experiences. What's needed is a *child-centred* approach, whereby the tasks set by the teacher are adapted as precisely as possible to the child's cognitive level.
- Regarding the *curriculum,* the greatest impact of his theory has been on science and maths. Teaching materials should consist of concrete objects that children can easily manipulate. But rather than trying to base a curriculum on Piagetian stages, it would be more useful to modify the curriculum in line with what's known about them, and not allow them to limit teaching methods (Ginsberg, 1981). However, even today, an understanding of number conservation remains a criterion for an *attainment target* in the UK National Curriculum for maths (Davis, 2003: see below).
- Central to a Piagetian perspective is the view that children learn from actions rather than from passive observation (*active self-discovery/discovery learning*). As far as *teaching methods* are concerned, teachers must recognise that each child needs to construct knowledge for itself, and that deeper understanding is the product of active learning (Smith *et al.*, 1998). Piaget's account of development could be used by those involved in early education as a *formalisation* of many of the assumptions underlying child-centred education.

Box 34.6 The role of the teacher in the Piagetian classroom

- It's essential for teachers to assess very carefully each individual child's current stage of cognitive development (this relates to the concept of readiness). The child can then be set tasks tailored to its needs which become *intrinsically motivating*.
- Teachers must provide children with learning opportunities that enable them to advance to the next developmental step. This is achieved by creating *disequilibrium* (see page 582). Rather than providing the appropriate materials and allowing children to 'get on with it', teachers should create a proper balance between actively guiding and directing children's thinking patterns, and providing opportunities for them to explore by themselves (Thomas, 1985).
- Teachers should be concerned with the *learning process* rather than its end product. This involves encouraging children to ask questions, experiment and explore. Teachers should look for the reasoning behind children's answers, particularly when they make mistakes.
- Teachers should encourage children to *learn from each other*. Hearing other (and often conflicting) views can help break down egocentrism, and working in pairs can promote long-lasting PT (e.g. Doise & Mugny, 1984). This has powerful implications for the British educational system (and any others), which from infant school through to university assesses understanding and knowledge at an individual level (Davis, 2003).

VYGOTSKY'S THEORY: THE CHILD AS APPRENTICE

Vygotsky didn't produce a fully formed theory or coherent body of research, and many of his ideas weren't spelled out in detail. His works were published in the former Soviet Union in the 1920s and 1930s, but weren't translated into English until the early 1960s (*Thought and Language,* 1962).

Lev Vygotsky (1896–1934)

Vygotsky and Piaget agree that development doesn't occur in a vacuum: knowledge is constructed as a result of the child's active interaction with the environment. But, as we've seen, for Piaget that environment is essentially *asocial* (so his account is described as *constructivist*. But for Vygotsky:

> ... Human nature cannot be described in the abstract; whatever course children's mental growth takes is to a large extent a function of the cultural tools that are handed down to them by other people ... (Schaffer, 2004)

So, for Vygotsky, cognitive development is a thoroughly *social* process (hence, he's a *social constructivist*). His aim was to spell out and explain how the higher mental functions (reasoning, understanding, planning, remembering, and so on) arise out of children's social experiences. He did this by considering human development in terms of three levels: the *cultural, interpersonal* and *individual*. He had much more to say about the first two than the latter, so we'll concentrate on these here.

The cultural level

Children don't need to 'reinvent the world anew' (as Piaget seemed to believe). They can benefit from the accumulated wisdom of previous generations; indeed, they cannot avoid doing so through interactions with caregivers. So each generation stands on the shoulders of the previous one, taking over the particular culture – including its intellectual, material, scientific and artistic achievements – in order to develop it further before handing it on, in turn, to the next generation (Schaffer, 2004).

ASK YOURSELF...

- Can you think of examples of cultural tools that might be especially important for children's cognitive development?

Cultural tools are what the child 'inherits'. These can be:

- *technological* (clocks, bicycles and other physical devices)
- *psychological* (concepts and symbols, such as language, literacy, maths and scientific theories)
- *values* (such as speed, efficiency, and power).

It's through such tools that children learn to conduct their lives in socially effective and acceptable ways, as well as understanding how the world works.

Schaffer (2004) gives the example of *computers* as a major – and relatively recent – cultural tool:

The computer: a powerful and pervasive cultural tool

There are few instances in history where a new technical invention has assumed such a dominant role in virtually all spheres of human activity as the computer... in the space of just a few decades computing expertise is regarded as an essential skill for even quite young children to acquire ...

The most essential cultural tool is *language.*

Box 34.7 The importance of language as a cultural tool

- It's the pre-eminent means of passing on society's accumulated knowledge: how others speak and what they speak about is the main channel of communicating culture from adult to child.
- It enables children to regulate their own activities.
- At about age seven, speech becomes internalised to form internal thought: an essential *social* function thus becomes the major tool for *cognitive* functioning.

The interpersonal level

It's here that culture and the individual meet, and it's the level at which Vygotsky made his major contribution.

Internalisation and the social nature of thinking

The ability to think and reason by and for ourselves (inner speech or verbal thought) is the result of a fundamentally *social* process. At birth, we're social beings capable of interacting with others, but able to do little either practically or intellectually, by or for ourselves. But gradually we move towards self-sufficiency and independence, and by participating in social activities our abilities become transformed. For Vygotsky, cognitive development involves an active *internalisation* of problem-solving processes that takes place as a result of mutual interaction between children and those with whom they have regular social contact (initially the parents, but later friends and classmates and teachers).

This is the reverse of how Piaget (at least initially) saw things. Piaget's idea of 'the child as a scientist' is replaced by the idea of 'the *child as an apprentice',* who acquires the culture's knowledge and skills through graded collaboration with those who already possess them (Rogoff, 1990). According to Vygotsky (1981):

Any function in the child's cultural development appears twice, or on two planes. First it appears on the social plane, and then on the psychological plane.

So, cognitive development progresses from the *intermental* to the *intramental* (from joint regulation to self-regulation).

Box 34.8 Pointing: an example of cultural development from the physical to the social

- Initially, a baby's pointing is simply an unsuccessful attempt to grasp something beyond its reach.

- When the mother sees her baby pointing, she takes it as an 'indicatory gesture' that the baby wants something, and so helps it, probably making the gesture herself.
- Gradually, the baby comes to use the gesture deliberately. The 'reaching' becomes reduced to movements which couldn't themselves achieve the desired object even if it were in reach, and is accompanied by cries, looks at the mother and eventually words.
- The gesture is now directed towards the mother (it has become a gesture 'for others'), rather than towards the object (it's no longer a gesture 'in itself': Meadows, 1995).

Scaffolding and the zone of proximal development (ZPD)

The *zone of proximal development* (ZPD) defines those functions that haven't yet matured but are in the process of maturing (Vygotsky, 1978). These could be called the 'buds' or 'flowers' rather than the 'fruits' of development. The actual developmental level characterises mental development *retrospectively,* while the ZPD characterises mental development *prospectively.*

ASK YOURSELF...

- What do you understand by this distinction regarding level of mental development? (See Box 34.9, page 595.)

Scaffolding refers to the kind of guidance and support adults provide children in the ZPD by which children acquire their knowledge and skills (Wood *et al.*, 1976; Wood & Wood, 1996). As a task becomes more familiar to the child and more within its competence, those who provide the scaffold leave more and more for the child to do until it can perform the task successfully. In this way, the developing thinker doesn't have to create cognition 'from scratch': there are others available who've already 'served' their own apprenticeship.

The internalised cognitive skills remain social in two senses. First, as mature learners we can 'scaffold' ourselves through difficult tasks (self-instruction), as others once scaffolded our earlier attempts. Second, the only skills practised to a high level of competence for most people are those offered by their culture: cognitive potential may be universal, but cognitive expertise is culturally determined (Meadows, 1995).

ASK YOURSELF...

- How does this distinction between cognitive potential and expertise relate to Dasen's (1994) assessment of Piaget's stages (see Cross-Cultural Study 34.1, page 590)?

Since the 1980s, research has stressed the role of social interaction in language development, especially the facilitating effects of the use of child-contingent language by adults talking with children (Meadows, 1995: see Chapter 19). This 'fit' between adult and child language closely resembles the concept of 'scaffolding'.

KEY STUDY 34.4 Scaffolding (or individual abilities are built on social support) (Wood *et al.*, 1976)

- Wood *et al.* found that on a construction task with four- to five-year-olds (fitting wooden blocks together with pegs to make a pyramid), different mothers used instructional strategies which varied in their levels of specificity. These ranged from general verbal encouragement to direct demonstration of a relevant action.
- No single strategy guaranteed learning, but the most efficient maternal instructors were those who combined general and specific interventions according to the child's progress.
- The most useful help is that which adapts itself to the learner's successes and failures (Bruner, 1983). An example would be using a general instruction initially until the child runs into difficulties. At this point, a more specific instruction or demonstration is given. This style allows the child considerable autonomy, but also provides carefully planned guidance in its ZPD.

Although 'scaffolding' doesn't actually explain how children internalise what the tutor provides, it draws attention to the conditions under which learning usually occurs. It also emphasises the essential *social-interactive* nature of these conditions (Schaffer, 2004).

According to Vygotsky, a more knowledgeable child can provide instruction and guidance for another, in order to bring the latter up to a similar level of competence (*peer tutoring:* Foot & Howe, 1998; Foot *et al.*, 1990).

As would be predicted from Vygotsky's theory, there's also evidence of scaffolding processes in everyday, naturalistic contexts. These are often linked to the transmission across generations of culturally valued skills, such as weaving among the Zinacauteco Mexicans and American mothers' involvement in their preschoolers' development of number (Durkin, 1995).

ASK YOURSELF...

- What would you say is the key difference between Vygotsky's and Piaget's theories?

An evaluation of Vygotsky's theory

- Vygotsky's theory clearly 'compensates' for one of the central limitations of Piaget's theory. As Segall *et al.* (1999) put it:

  Piaget produced a theory of the development of an 'epistemic subject', an idealised, non-existent individual, completely divorced from the social environment.

For Vygotsky, culture (and especially language) plays a key role in cognitive development: the development of the individual cannot be understood – and indeed cannot happen – outside the context of social interaction.

- While Vygotsky's theory hasn't been tested cross-culturally as Piaget's has, it has influenced cross-cultural psychology through the development of *cultural psychology* (e.g. Cole, 1990: see Chapter 47) and related approaches, such as 'socially shared cognition' (Resnick *et al.*, 1991) and 'distributed cognition' (Salomon, 1993). According to all these approaches:

  ... cognitive processes are not seen as exclusively individual central processors, but ... are situation specific ... therefore cognition is not necessarily situated 'within the head' but is shared among people and settings ...'. (Segall *et al.*, 1999)

- Although Vygotsky didn't carry out much empirical research himself, the specific nature of many of his ideas has made it possible for others to follow them up. This has resulted in a substantial body of research on scaffolding, peer tutoring and other aspects of the educational process (see below).
- But, in contrast with Piaget's theory, Vygotsky's isn't truly developmental. His ideas are based on a 'prototype' child, who functions in the same way at age two or twelve: nothing is said about changes in the processes underlying learning (such as attention, memory and intellectual capacities) and how these affect social interaction at different ages.
- Schaffer (2004) believes that his neglect of *emotional* factors is a serious omission: he makes no reference to struggles, the frustrations of failure, the joys of success, or generally what *motivates* the child to achieve particular goals:

  ... While cognition was given a social appearance, Vygotsky's treatment of the child is as 'cold' as Piaget's ... (Schaffer, 2004)

Applying Vygotsky's theory to education

In describing Vygotsky's most important ideas, we've seen how many of them are related (directly or indirectly) to the learning process – and, hence, to education. Examples include the ZPD, scaffolding and peer tutoring. According to Davis (2003):

By emphasizing the social nature of development, Vygotsky's theory is not only a theory of learning, it also offers a theory of teaching, since language is the prime medium for sharing knowledge in formal contexts such as schools and informally in the home ...

Box 34.9 Applying the concept of the ZPD to education

Suppose a child is currently functioning at level 'x' in terms of attainment. Through innate/environmental means, the child has the potential to reach level 'x + 1'.

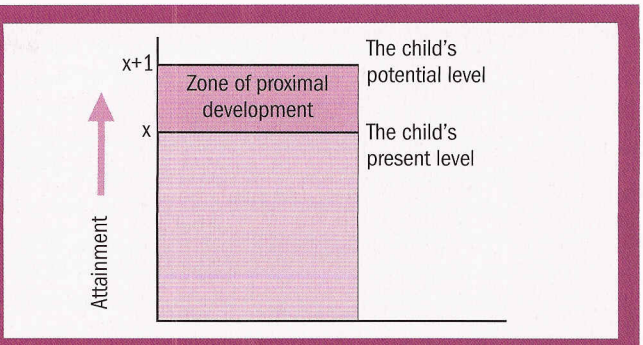


Figure 34.8 Vygotsky's zone of proximal development

The area between 'x' and 'x + 1' is the child's ZPD. The ZPD may be different for individual children, and children with large ZPDs will have a greater capacity to be helped than those with small ZPDs. Irrespective of the ZPD's size, Vygotsky saw the teacher as being responsible for giving children the cues they need or taking them through a series of steps towards the solution of a problem.

(Based on Sutherland, 1992)

In *collaborative learning*, children at similar levels of competence work together, either in pairs or groups. Slavin's (1990) *Student Teams Achievement Divisions* (STAD) involves small groups of varying ability, gender and ethnic background working on a topic. These groups show greater achievement than controls taught by more conventional methods. Educators now believe that both collaborative learning and *peer tutoring* can offer an effective environment for guiding a child through its ZPD. This may be because these settings encourage children to use language, provide explanations, and work cooperatively or competitively, all of which help produce cognitive change (Pine, 1999).

Vygotsky defines intelligence as the capacity to learn from instruction. Rather than teachers playing an *enabling* role, Vygotsky believes they should guide pupils in paying attention, concentrating, and learning effectively (a *didactic* role: Sutherland, 1992). By doing this, teachers scaffold children to competence.

Box 34.10 Vygotsky and the National Curriculum

In the UK, the past 20 years have seen an almost complete U-turn in educational policy and practice. The emphasis has shifted from *child-centred* to *curriculum-centred* education (Davis, 2003).

- The Plowden Report (1967) ('Children and their primary schools') stated that 'at the heart of the educational process lies the child'. In the mid-1980s, the then Secretary of State for Education declared that 'at the heart of the educational process lies the curriculum'.
- These two views can be seen as reflecting Piaget and Vygotsky's theories, respectively.

- The Education Reform Act 1988 introduced a compulsory National Curriculum (NC) for all 5–16-year-olds in England and Wales. English, maths and science were identified as 'core' subjects, and *attainment targets* were specified (descriptions of the knowledge children should have acquired as they work through the system). These targets at *key stages* provide the benchmark for assessment at ages 7, 11, 14 and 16.
- Assessment involves *criterion referencing* (as opposed to *norm referencing*) – that is, measuring a child's performance relative to a specified criterion (a given attainment target). The assessment tests are 'standard assessment tasks' (SATs).
- Sutherland (1992) argues that Vygotsky didn't:

  ... advocate mechanical formal teaching where children go through the motions of sitting at desks and passing exams that are meaningless to them ... On the contrary, Vygotsky stressed intellectual development rather than procedural learning ...

- Vygotsky rejected any approach advocating that teachers have rigid control over children's learning. Rather, as with Piaget, teachers' control over children's activities is what counts. Teachers extend and challenge children to go beyond where they otherwise could have.

BRUNER'S THEORY

Similarities and differences between Bruner, Piaget and Vygotsky

Bruner has helped to extend Vygotsky's ideas, and to apply them in the context of education (for example, the concept of scaffolding: see above). Bruner has also been influenced by Piaget, and they share certain basic beliefs, in particular that:

- children's underlying cognitive structures mature over time, so that they can think about and organise their world in an increasingly complex way
- children are actively curious and explorative, capable of adapting to their environment through interacting with it. Abstract thinking grows out of action: competence in any area of knowledge is rooted in active experience and concrete mental operations.

However, there are also some basic areas of disagreement between Bruner and Piaget, stemming from Vygotsky's influence. In particular, Bruner stresses the role of language and interpersonal communication, and the need for active involvement by expert adults (or more knowledgeable peers) in helping the child to develop as a thinker and problem-solver. Language plays a crucial part in the scaffolding process. He also sees instruction as an essential part of the learning process, both in naturalistic and educational settings.

Jerome Bruner (born 1915)

Modes of representation

Unlike Piaget, Bruner (1966) doesn't identify stages of development as such. Instead, he describes three *modes of representing the world,* different forms that our knowledge and understanding can take. He isn't, therefore, concerned exclusively with cognitive growth but also with knowledge in general. The three modes are the *enactive, iconic,* and *symbolic,* which develop in that order.

The enactive mode

At first, babies represent the world through *actions.* Any knowledge they have is based upon what they've experienced through their own behaviour (this corresponds to Piaget's *sensorimotor stage*). Past events are represented through appropriate motor responses. Many of our motor schemas, such as 'bicycle riding, tying knots, aspects of driving, get represented in our muscles, so to speak', and even when we have the use of language, it's often extremely difficult to describe in words how we do certain things.

ASK YOURSELF...

- Try describing how to tie a shoelace.

Through recurrent events and environmental conditions, we build up virtually automatic patterns of motor activity which we 'run off' as units in the appropriate situation. Like Piaget, Bruner sees the onset of *object permanence* as a major *qualitative* change in the young child's cognitive development.

The iconic mode

An icon is an *image,* so this form of representation involves building up mental images of things we've experienced. Such images are normally composite, that is, made up of a number of past encounters with similar objects or situations.

ASK YOURSELF...
- To which stage(s) of Piaget's theory does the iconic mode correspond?

This mode corresponds to the last six months of the sensorimotor stage (where schemas become interiorised) and the whole of the *pre-operational* stage, where the child is at the mercy of what it perceives in drawing intuitive conclusions about the nature of reality: things are as they *look*.

The symbolic mode

Bruner's main interest was in the *transition* from the iconic to the symbolic mode. He and Piaget agree that a very important cognitive change occurs at around 6–7 years. For Piaget, this is the start of *logical operations* (albeit tied to concrete reality), while Bruner sees it as the appearance of the *symbolic mode*. Language comes into its own as an influence on thought. The child is now freed from the immediate context and is beginning to be able to 'go beyond the information given' (Bruner, 1957).

KEY STUDY 34.5 The transition from iconic to symbolic modes (Bruner & Kenney, 1966)

- Bruner and Kenney arranged nine plastic glasses in a 3 x 3 matrix (as shown in Figure 34.9). Three- to seven-year-olds were familiarised with the matrix.
- The glasses were then scrambled, and the children were asked to put them back as they were before (the *reproduction task*). In the *transposition task*, the glasses were removed from the matrix, and the glass which had been in the bottom right-hand square was placed in the bottom left-hand square; the child had to rebuild the matrix in this transposed manner.

ASK YOURSELF...
- Which task would you expect children to find easier – and why?

- Children generally could reproduce it earlier than they could transpose it. The reproduction task involves the *iconic mode* (60 per cent of the five-year-olds could do this, 72 per cent of the six-year-olds, and 80 per cent of the seven-year-olds). But the transposition task involves the *symbolic mode* (the results were 0 per cent, 27 per cent and 79 per cent, respectively).
- Clearly, the five-year-olds were dominated by the visual image of the original matrix, while the six- to seven-year-olds translated their visual information into the symbolic mode. They relied upon verbal rules to guide them, such as, 'It gets fatter going one way and taller going the other'. So, a child using images but not symbols can reproduce but not restructure.

Applying Bruner's theory to education

The 'spiral curriculum'

Bruner's modes of representation lie at the heart of the *'spiral curriculum'*, according to which the principles of a subject come to be understood at increasingly more complex levels of difficulty. Like Vygotsky, Bruner was unhappy with Piaget's concept of 'readiness', and proposed a much more active policy of intervention, based on the belief that 'any subject can be taught effectively in some intellectually honest form to any child at any stage of development' (Bruner, 1966).

Educators need to provide learners with the means of grasping the structure of a discipline, that is, the underlying principles and concepts (rather than just mastering factual information). This enables learners to go beyond the information given, and develop ideas of their own. Teachers also need to encourage learners to make links, and to understand the relationships within and between subjects (Smith *et al.*, 1998).

INFORMATION-PROCESSING THEORIES

According to Bee (2000), it's more accurate to talk of the information-processing (IP) *approach* than a distinct IP theory of cognitive development. This approach grew out of, and in some ways represents a reaction to, Piaget's theory (Pine, 1999). Like Piaget, IP theorists believe there are psychological structures in people's minds that

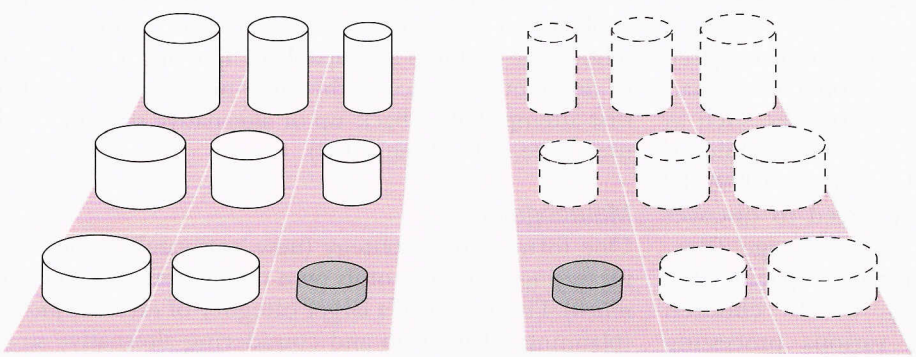

Figure 34.9 The two arrangements of glasses used by Bruner & Kenney (1966)

explain their behaviour, and which are essentially independent of the individual's social relationships, social practices, and cultural environment (Meadows, 1995).

Box 34.11 How different are Piaget's and the IP approaches?

- IP theorists can explain cognitive development (the child makes better and more efficient use of basic cognitive processes) *without* having to assume any global reorganisation of the cognitive system (*qualitatively different stages*) as proposed by Piaget. For example, based on research using Piagetian-type tasks, Siegler (1976) claims that what changes as children develop is their acquisition of increasingly complex rules for problem-solving.
- Consistent with Piaget's theory, Siegler's research suggests that there's a sequence in children's acquisition of new strategies, but this is still very different from identifying developmental stages. Nevertheless, we shouldn't assume that a child either has or doesn't have a particular strategy in its repertoire at any time. When learning a new strategy in maths, for example, a child may forget to use it all the time, or fail to see that it can be applied to new problems. One important developmental change is knowing where and when to use new strategies (Siegler, 1989). This is related to *metacognition* (see text below).
- IP accounts see development unfolding in a *continuous* way (more like Vygotsky than Piaget). When the child is able to move from pre-operational to concrete operational thinking (for example, can conserve), its *processing capacity* has increased: s/he can now hold two things in mind simultaneously. So, what underlies the apparent *qualitative* change in thinking is actually a *quantitative* change in processing capacity (Slater *et al.*, 2003).
- According to Bee (2000), some of the changes Piaget attributed to new mental structures can be more simply explained in terms of increased *experience with tasks and problems*, and *faster and more efficient processing* of information (again, all *quantitative* changes). At the same time:

There also seems to be a real qualitative change in the complexity, generalisability, and flexibility of strategies used by the child.

Underlying the IP approach is the *computer analogy* (see Chapters 2, 17 and 20). This examines more closely than Piaget's theory how major cognitive processes, such as memory and attention, come into play when children deal with particular tasks and problems (Pine, 1999). To understand cognitive *development*, we need to discover what changes in any systematic way with age (Bee, 2000). Is it the system's basic storage capacity that increases (a 'hardware' difference), or do children become more efficient in using various processing strategies (a 'software' difference)? Of course, *both* types of change might be involved: brain growth occurs which, in turn, allows more functional development. But, at present, we know rather more about the *how* of change than the *why* (Schaffer, 2004).

To study the claim that children become better information-processors as they develop, IP theorists use *task analysis*.

Box 34.12 Task analysis

To understand why children cannot solve problems that adults can, we need to understand a particular task's *component steps* (Oakhill, 1984). For example, five elements are necessary to solve the following problem: 'If Ann is not as bad as Betty, and Betty is not as bad as Carole, who is the best?'

1. The child must perceive and encode the important statements (premises) contained in the question, which involves *attending* to it (see Chapter 13).
2. The premises must be stored in *working memory* (WM: see Chapter 17).
3. They must be combined in memory to form an *integrated representation*.
4. The question must be *encoded*.
5. The representation of the premises must be *scanned* to answer the question or formulate a *conclusion* about it.

IP theorists argue that children fail to solve such problems correctly because of errors in encoding the problem, being unable to hold information in memory for long enough, or because holding it in memory may interfere with other task performance (Trabasso, 1977).

Keeney *et al.* (1967) gave children of different ages a series of pictures to remember. Before being tested on recall, most eight- to-ten-year olds could be seen mouthing the picture series (*rehearsal*), while the five-year-olds didn't do this. Although the younger children recalled far fewer items than the older children, they could be taught the rehearsal strategy and then performed as well as the older children. So, their memory was just as good, but they didn't use it as efficiently as the older children.

A large amount of research has found that as children grow, they acquire more and more powerful strategies for remembering, use them more efficiently and flexibly, and apply them to an increasing variety of problems. Also, school-age children are capable of applying a wider range of different strategies to the same problem, so that if the first attempt fails, a back-up or alternative strategy can be used (Bee, 2000; Pine, 1999).

Metacognition

One form of new strategy (new 'software') is the child's increasing awareness of its own mental processes (*metacognition*). This is part of a larger category of *executive processes* (planning what to do and considering alternative strate-

gies). It may be precisely such metacognitive/executive skills that gradually emerge with age. Performance on a whole range of tasks will be better if the child can monitor its own performance, and recognise when a particular strategy is required or not. This self-monitoring improves fairly rapidly, beginning at school age (Bee, 2000).

According to Pascual-Leone (1980) and Case (1985), children don't use just one cognitive strategy in solving Piagetian tasks (as Piaget believed), but several: just how many is correlated with a problem's difficulty. Like Oakhill (1984), Pascual-Leone and Case also see WM as storing the information necessary to solve problems. The amount of memory space necessary is also correlated with the problem's complexity and, as the child develops, so available memory space increases. Certain strategies also become *automatic* with practice, and so require less space in memory (see Chapter 17). An adult, for example, would instantly 'see' that (10 + 6) – (10 + 6) equals zero. A child, however, would require time to solve this problem, since each component must be stored in memory before a solution can be reached.

Applying IP theories to education

One strength of the IP approach is its emphasis on memory and young children's limited capacity to process information. As well as memory's importance in the child's ability to operate effectively, knowledge also has a considerable influence on learning, and the more children know about a situation, the more successfully they'll deal with it. As Sutherland (1992) has noted:

> One of the teacher's main roles is to help children find strategies for reducing their memory load – for instance to write down a list of the facts they need to solve a maths problem.

While young children can add numbers together when two digits are involved (e.g. 22 + 56), they make errors when three digits are used (Van Lehn, 1983). For example, faced with the problem:

```
231  +
 42
```

young children tend either to ignore the third column and arrive at 73 as the answer, or to muddle up the hundreds and tens columns to produce 673. Van Lehn uses the term *repair* to refer to the process by which addition involving three digits can be successfully achieved. This process implies a teacher-led approach to teaching mathematics. However, IP theories also see metacognition as playing a vital role. In the case of learning to read, the child needs to be aware of which words it knows and doesn't know, which sentences it understands and doesn't understand, and how to get the information it needs. A variety of research shows that younger and poorer readers are less skilled at all these metacognitive tasks compared with older and better readers (Flavell *et al.*, 1993: see Chapter 40).

CONCLUSIONS

Piaget's theory revolutionised the way that cognitive development has been investigated and understood. Both Vygotsky's theory and the IP approach challenge some of Piaget's basic assumptions, but they adopt radically different views from each other as to what cognitive development involves. While Vygotsky emphasises the social nature of cognitive change, both Piaget and the IP approach see development as occurring quite *independently* of social interaction. Bruner's theory reflects the influence of both Piaget and Vygotsky. All four theories have contributed to our understanding of the education of young children.

CHAPTER SUMMARY

- Piaget sees **intelligence** as **adaptation to the environment**, and he was interested in how intelligence changes as children grow (**genetic epistemology**). Younger children's intelligence is **qualitatively different** from that of older children.
- **Cognitive development** occurs through the **interaction** between innate capacities and environmental events. It progresses through a series of **hierarchical**, **invariant** and **universal stages**: the **sensorimotor**, **pre-operational**, **concrete operational** and **formal operational** stages.
- Underlying cognitive changes are **functional invariants**, the most important being **assimilation**, **accommodation** (which together constitute **adaptation**) and **equilibration**. The major cognitive structures that change are **schemas/schemata**.
- During the **sensorimotor stage**, frequent interaction with objects ultimately leads to **object permanence**, which is fully developed when the child can infer **invisible displacements**.
- By the end of the sensorimotor stage, schemas have become '**interiorised**'. **Representational/make-believe play**, like **deferred imitation**, reflects the **general symbolic function**.
- **Pre-operational children** have difficulty in **seriation tasks** and also display **syncretic thought**, **transductive reasoning**, and **animism**. **Centration** is illustrated by the **inability to conserve**. Pre-operational children are also **egocentric**.
- During the **concrete operational stage**, logical operations can be performed only in the presence of actual or observable objects. Some types of conservation appear before others (**horizontal décalage**), and a child who's mastered all kinds of classification but not all kinds of conservation displays **vertical décalage**.
- **Formal operational thinkers** can manipulate **ideas** and **propositions** ('second order' operations) and think **hypothetically**.
- Four- and five-year-olds are capable of **perspective-taking**, enabling them to attribute **false beliefs** to

other people. This is a crucial feature of the child's **theory of mind**.

- While basic cognitive processes may be **universal**, how these are brought to bear on specific contents is influenced by **culture**.
- Piaget's stage theory is a **domain-general** theory, which many psychologists more recently have rejected in favour of **domain-specific** approaches.
- Central to Piagetian views of the educational process is **active self-discovery/discovery learning**. Teachers assess each individual child's current stage of cognitive development to set intrinsically motivating tasks, and provide learning opportunities that create disequilibrium.
- According to Vygotsky, the initially helpless baby actively **internalises** problem-solving processes through **interaction with parents**. Vygotsky's **child apprentice** acquires cultural knowledge and skills through **graded collaboration** with those who already possess them (**scaffolding**).
- The most useful assistance a mother can give her child with task performance is to use general instruction initially until the child experiences difficulties, then give more specific instruction. This relates to Vygotsky's **zone of proximal development** (ZPD).
- For Vygotsky, intelligence is the capacity to learn from instruction. Teachers perform a **didactic role**, guiding pupils in paying attention, concentrating, and learning effectively. In this way, children are scaffolded.
- Bruner shared Piaget's belief that abstract thinking grows out of **action.** He was also influenced by Vygotsky's ideas and stressed the **role of language** in the scaffolding process, and the need for the active involvement of more expert others.
- Bruner identifies three **modes of representation**, the **enactive**, **iconic** and **symbolic**. He stressed the transition from iconic to symbolic at ages six to seven, seeing logical thought as dependent on language. This implies that language training can speed up cognitive development.
- **Information-processing** (IP) theories are based on the **computer analogy**. **Task analysis** is used to study the development of children's 'mental programs' and strategies for processing information.
- While children appear to acquire new strategies in a particular sequence, this isn't equivalent to a Piagetian stage. Nevertheless, children can be inconsistent when using new strategies. Improvement with age is related to improved monitoring of performance (part of **metacognition**).
- Emphasis on **memory** and young children's **limited IP capacity** can explain why they're poorer at tasks involving memorising and reading. Storing knowledge linguistically is a vital prerequisite of successful IP performance. Teachers have a crucial role to play in helping children to find strategies for reducing memory load.

Links with other topics/chapters

- The inability to engage in representational/make-believe play, and the general inability to use imagination, is a characteristic of *autistic children* (Chapter 40).
- Piaget and Inhelder's very strong views have stimulated an enduring surge of research on egocentrism and perspective-taking (Siegal, 2003). Its 'modern' form is *theory of mind* (ToM) research, especially in relation to *autism* (Chapter 40).
- How children from *non-western cultures* perform on conservation tasks originally designed for Swiss samples will depend on the familiarity of the materials used, how the instructions are communicated, and the child's grasp of 'being tested' (Schaffer, 2004) (Chapter 47)
- The issue of whether development is best understood in terms of stages doesn't apply just to children. In fact it becomes arguably more relevant and controversial in relation to *adulthood* (Chapter 38). The related issue of *continuity/discontinuity* of development is especially relevant in understanding the impact of *early experience on later behaviour/personality* (Chapter 32).
- According to Moghaddam (2002), stage models are compatible with, and supportive of, the ideal of self-contained *individualism* that's so central to US culture – and, through that, becoming so influential throughout the world. Such models typically depict development as primarily dependent on factors *within* the individual, with social factors playing little/no part. This makes them *culturally biased* (Chapter 47).
- The reduction of egocentrism through peer interaction has major implications for children's *moral development* (Chapter 35).
- Evidence exists to show that children's individual learning may be enhanced without direct interaction with peers, but simply having peers present in the same room performing the same task (Davis, 2003). This describes *social facilitation* through the *co-action effect* (Chapter 31).
- A major difference between Piaget and Vygotsky concerns the importance they attached to *language's influence on cognitive development* (Chapter 18).
- Bruner's concept of 'going beyond the information given' is important for understanding *indirect theories of perception* (such as Gregory's) (Chapter 15).
- A way of evaluating the IP approach is to consider the debate between supporters of *soft and hard artificial intelligence* (AI) (Chapter 20).
- Impaired executive functioning is one proposed explanation of *autism* (Chapter 40).

MORAL DEVELOPMENT

INTRODUCTION AND OVERVIEW

At birth, we're *amoral*, lacking any system of personal values and judgements about right and wrong. By adulthood, though, most of us possess morality. Psychologists aren't interested in morality as such, but in the process by which it's acquired. The nature of that process is seen very differently by different psychological theories, which attempt to answer quite different questions.

According to Haste *et al.* (1998), historically four main questions have been asked about moral development.

1. How do conscience and guilt develop, acting as sanctions on our misdeeds? This relates to Freud's *psychoanalytic theory*.
2. How do we come to understand the basis of rules and moral principles, so that we can make judgements about our own and others' behaviour? This relates to the *cognitive–developmental theories* of Piaget, Kohlberg, and Eisenberg.
3. How do we learn the appropriate patterns of behaviour required by our culture? This relates to *learning theories*, including Bandura's *social learning theory*.
4. How do we develop the moral emotions that motivate our concern for others? Eisenberg's theory is also relevant here.

The relationship between morality and human nature has been debated by philosophers for thousands of years. According to Rousseau (1762), humans are 'naturally' good, but this natural goodness may be constrained and distorted by external factors. Only sociobiologists (such as Wilson, 1975: see Chapter 2) among modern-day scientists agree with this view of morality as innate. While we may like to believe that our actions are governed by higher moral principles, the reality is that 'The genes hold culture on a leash' (Wilson: see Chapter 30).

In contradiction of Wilson's claims, all the major theories to be discussed in this chapter share the assumption that the acquisition of morality is part of the wider process of *socialisation*. In other words, morality develops according to the same principles which govern the development of other aspects of socialised behaviour (see Chapter 2).

FREUD'S PSYCHOANALYTIC THEORY

Freud's account of moral development is closely related to other aspects of his psychoanalytic theory, in particular the *structure of the personality* and the *stages of psychosexual development*.

The psychic apparatus

Freud believed that the personality (or *psychic apparatus*) comprises three parts, the id, ego and superego (see Figure 35.1).

- The *id:*

  ... contains everything that is inherited, that is present at birth, that is laid down in the constitution – above all, therefore, the instincts ... (Freud, 1923)

  The wishes and impulses arising from the body's needs build up a pressure or tension (*excitation*), which demands immediate release or satisfaction. Since the id's sole aim is to reduce excitation to a minimum, it's said to be governed by the *pleasure principle*. It is – and remains – the infantile, presocialised part of the personality. The two major id instincts are sexuality and aggression (see Chapter 29).
- The *ego* is:

  ... that part of the id which has been modified by the direct influence of the external world ... (Freud, 1923)

  It can be thought of as the 'executive' of the personality, the planning, decision-making, rational, and logical part of us. It enables us to distinguish between a wish and reality (which the id cannot do), and is governed by the *reality principle*. While the id demands immediate gratification of our needs and impulses, the ego will postpone satisfaction until the appropriate time and place (*deferred gratification*):

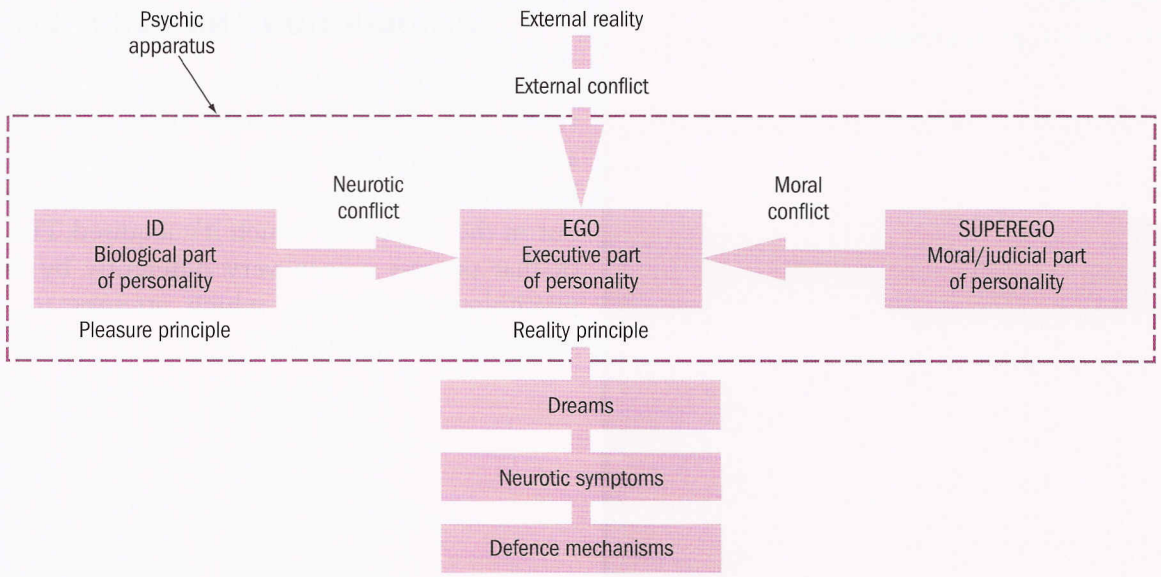

Figure 35.1 The psychic apparatus, showing sources of conflict and ways of resolving it

> The ego seeks to bring the influence of the external world to bear upon the id and its tendencies ... For the ego, perception plays the part which in the id falls to instinct. The ego represents ... reason and common sense, in contrast to the id, which contains the passions ... (Freud, 1923)

◎ Not until the *superego* has developed can we be described as moral beings. It represents the *internalisation* of parental and social moral values:

> It observes the ego, gives it orders, judges it and threatens it with punishment, exactly like the parents whose place it has taken ... (Freud, 1933)

It is in fact the *conscience* which threatens the ego with punishment (in the form of guilt) for bad behaviour, while the *ego-ideal* promises the ego rewards (in the form of pride and high self-esteem) for good behaviour. These correspond to the punishing and rewarding parents respectively.

Psychosexual development

Although the id, ego and superego develop within the individual in that order, this isn't strictly part of Freud's developmental theory. According to his theory of *infantile sexuality,* sexuality isn't confined to physically mature adults, but is evident from the moment of birth. So, babies and young children have sexual experiences and are capable of sexual pleasure, which is derived from the rhythmical stroking or stimulation of any part of the body. However, different parts of the body (the *erogenous zones*) are particularly sensitive at different times during infancy and childhood, and become the focus of sexual pleasure (and frustration).

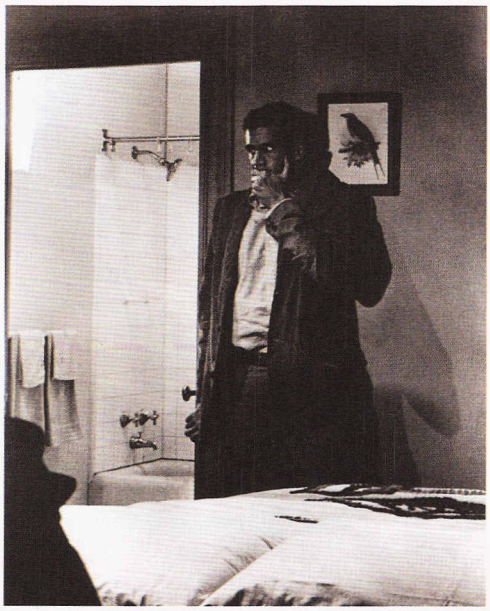
The sequence of these psychosexual stages is determined by *maturation* (it's biologically programmed), but how a child is treated by others (especially the parents) is crucial. Either excessive gratification or extreme frustration can result in an individual getting emotionally 'stuck' (*fixated*) at the particular stage at which this occurs, producing associated *adult personality traits.* For example, *anal retentive traits* include parsimony (miserliness) and obstinacy.

Box 35.1 Freud's stages of psychosexual development

- **Oral stage (0–1 year):** The nerve-endings in the mouth and lips are highly sensitive, and the baby derives pleasure from sucking for its own sake (*non-nutritive sucking*). In the earlier *incorporative substage,* the major oral activities are sucking, swallowing and mouthing. In the later *biting/aggressive substage,* hardening gums and erupting teeth make biting and chewing sources of pleasure.
- **Anal stage (1–3 years):** The anal cavity and sphincter muscles of the bowel are now the main sources of pleasure. In the earlier *expulsion substage,* the child undergoes potty-training and so has its first encounter with external restrictions on its wish to defecate where and when it pleases. Parental love is no longer unconditional, but now depends on what the child does. In the later *retention substage,* parents come to be seen for the first time as authority figures:

  > By producing them [the contents of the bowels] ... [the infant] can express his active compliance with his environment, and by withholding them, his disobedience ... (Freud, 1905)

- **Phallic stage (3–5/6 years):** Sensitivity is now concentrated in the genitals, and masturbation (in both sexes) becomes a new source of pleasure. The child becomes aware of anatomical sex differences ('*phallic*' comes from the Greek word *phallus* meaning penis), which marks the beginning of the Oedipus complex. The name derives from the classical Greek tragedy *Oedipus Rex,* in which Oedipus kills his father and marries his mother. Both boys and girls experience conflicting emotions in relation to their same- and opposite-sex parents, and how successfully these conflicts are resolved is crucial for future personality development. The child's *superego* and *sex role* are acquired through resolution of the Oedipus complex.



A scene from Pasolini's (1967) film of Sophocles' Greek tragedy, *Oedipus Rex*, who unknowingly kills his father and marries his mother

- **Latency period (5/6 to puberty):** The sexual preoccupations of the earlier years are *repressed* (made unconscious), which allows the child's energies to be channelled into developing new skills and acquiring new knowledge. The balance between the id, ego and superego is relatively greater than at any other time in the child's life.
- **Genital stage (puberty–maturity):** Latency represents the calm before the storm of puberty, which marks the beginning of adolescence. The relative harmony within the child's personality is disrupted by the id's powerful new demands in the form of heterosexual desires.

The Oedipus complex, identification and the superego

A boy, like a girl, takes his mother as his first love-object (see Chapter 32). Starting at about three, a boy's love for his mother becomes increasingly passionate, and he doesn't wish to share her with anyone. The boy is also jealous of his father, who already 'possesses' her, and wants him out of the way ('dead'), so that he can have his mother all to himself. However, his father is bigger and more powerful than he is, and he eventually becomes afraid that his father will punish him by cutting off his penis (*fear of castration/castration anxiety*). He reaches this conclusion partly as a result of previous punishments for masturbation, and partly based on his observation that females don't have a penis.

To resolve the dilemma, the boy *represses* his desire for his mother and his hostile feelings for his father, and *identifies* with his father (he comes to act, think and feel as if he were his father). Through this *identification with the aggressor,* a boy acquires the superego and the male sex role (see Chapter 36).

Norman Bates (Anthony Perkins), the main character in Hitchcock's *Psycho*, identifies very strongly with his dead mother. He attempts, unconsciously, to 'keep her alive' by, for example, dressing up in her clothes

As for the girl, her Oedipus complex (sometimes referred to as the *Electra complex*) begins with the belief that she's already been castrated. She blames her mother for her lack of a penis, and experiences penis envy (she wants what males have). But she eventually realises that this is unrealistic, and substitutes the wish for a penis with the wish for a baby. This causes her to turn to her father as a love-object, in the hope that he'll provide her with a (preferably male) baby.

In order to identify with the mother, the girl must give up her father as a love-object and move back to her mother (while boys only have to make one 'move', from the mother to the father). However, Freud was much less sure about *why* the girl identifies with the mother than he was about the boy's motive for identifying with the father. The stronger the motive, the stronger (or more complete) the identification, which in turn makes for a stronger superego. So, boys' fear of castration is associated with a strong identification with the father (the 'aggressor') and a strong superego. As Freud (1924) says:

> The fear of castration being thus excluded in a little girl, a powerful motive also drops out for the setting up of a superego.

One suggestion Freud made was that the girl may fear loss of the mother's love. To keep the mother 'alive' inside her, she internalises her, becoming the 'good' child that her mother would want her to be (*anaclitic identification*). But what he was quite sure about was that identification with the mother is less complete. The girl's love for her father doesn't have to be as thoroughly abandoned as the boy's for his mother, and her Oedipus complex doesn't have to be so completely shattered (Mitchell, 1974). Consequently, females have a weaker superego and their identity as separate, independent persons is also less well developed.

ASK YOURSELF...

- Do you agree with Freud regarding females' moral inferiority?

CRITICAL DISCUSSION 35.1: Are females morally and sexually inferior to males?

- Because her identification with the mother is less complete, the girl relies more on external authority figures throughout her childhood, and has to be more compliant, and less 'naughty' (there's no equivalent of 'boys will be boys'). It's through his strong identification with the father that the boy achieves independence, which the girl will have to try to achieve in adolescence. According to Mitchell (1974):

> Many women, though nominally they leave home, understandably, never make it.

- But there's little evidence to support this view. For example, Hoffman (1975) reviewed several studies in which children were left alone and tempted to violate a prohibition (such as looking round to see a toy placed on a table behind them). There were usually no overall gender differences, but, if anything, girls were *better* able to resist temptation than boys were.
- As we noted earlier, Freud saw women as having to make do with babies as penis-substitutes, a view that has aroused fierce criticism, particularly from feminist psychologists (see Chapter 47). For example, Horney

(1924) and Thompson (1943), both eminent psychoanalysts, argued that what girls (and women) envy isn't the penis as such, but males' superior social status (the penis is a *symbol* for male privilege). Moreover, it's men, not women, who equate lack of a penis with inferiority!

An evaluation of the Oedipus complex

- Critical Discussion 35.1 has considered some of the criticisms of Freud's account of sex differences in morality which follows from his theory of the Oedipus complex ('the central phenomenon of the sexual period of early childhood': Freud, 1924).
- Another criticism concerns its potential *cultural bias.* Freud assumed that the Oedipus complex was a universal phenomenon, but even if true for western cultures, the Oedipus complex may not apply to every culture or to all historical periods (Segall *et al.*, 1990).

CROSS-CULTURAL STUDY 35.1

Trobriand Island boys and their fathers (Malinowski, 1929)

- Among the Trobriand Islanders of Papua, New Guinea, boys were traditionally disciplined by their maternal uncle (their mother's brother), rather than by their own biological father. It was an uncle's role to guide his nephew through to adulthood. Such societies are described as *avuncular*.
- However, the father remained the mother's lover. Hence, the two roles (disciplinarian and mother's lover) were adopted by *different* men, whereas in Viennese society at the time that Freud was proposing his theories, the boy's father played *both* roles.
- By explaining the boy's hostility towards the father wholly in terms of sexual jealousy, Freud overlooked the possibility that he resented his father's *power* over him (Segall *et al.*, 1990).
- What Malinowski found was that a Trobriand Island boy's relationship with his father was very good, free of the love–hate ambivalence which is central to Freud's Oedipal theory. By comparison, the relationship with the uncle wasn't usually so good.
- However, this doesn't necessarily mean that Malinowski was right and Freud was wrong (Price & Crapo, 1999). Segall *et al.* (1990) suggest that more societies need to be examined, including both western and avuncular.

- Freud (1909) cited his case study of 'Little Hans' as supporting his Oedipal theory. This five-year-old developed a phobia of being bitten by a horse, which Freud interpreted as a fear of castration (see Chapter 44). A common criticism made of Freud's developmental theory as a whole is that it was based largely on the study of his adult patients. This makes the case of Little Hans especially important, because he was Freud's only child patient.

Freud saw Hans as a 'little Oedipus', having formulated his theory four years earlier (in *Three Essays on the Theory of Sexuality,* 1905). Hence, the case study is biased and provides no independent evidence to support Freud. In addition, Hans's therapy was conducted mainly by his own father, a supporter of Freud's ideas! Even more seriously, perhaps, other psychoanalytic theorists have provided alternative explanations of Hans's fear of horses, including Bowlby (1973) who reinterpreted the case in terms of attachment theory (see Chapter 32).

ASK YOURSELF...

- What kind of independent evidence might be considered valid?
- Why is it a problem that Hans's therapy was conducted by his own father?
- How do you think Bowlby might have reinterpreted Hans's fear of horses?

Bee (2000) maintains that attachment research provides a good deal of support for the basic psychoanalytic hypothesis that the quality of the child's earliest relationships affects the whole course of later development. Both Bowlby (1973) and Erikson (1963: see Chapter 37) regard early relationships as *prototypes* of later relationships. Despite the considerable evidence showing that all types of early privation are reversible (see Chapter 32), and accepting all the criticisms of the Oedipal theory, belief in the impact of early experience is a lasting legacy of Freud's developmental theory.

COGNITIVE–DEVELOPMENTAL THEORIES

According to Haste *et al.* (1998), the question regarding moral rules, principles, and judgements (see *Introduction and overview*) has dominated research on moral development for 30 years, through work within the *cognitive–developmental theoretical framework.* While Kohlberg's theory has been the focus of research during this time, Piaget (1932) pioneered this approach to moral development. Cognitive–developmental theories maintain that it's the reasons *underlying* behaviour, rather than the behaviour itself, which make it right or wrong.

Piaget's theory

Piaget argued that morality develops gradually during childhood and adolescence. While these changes are usually referred to as qualitatively different stages of moral development, Piaget explicitly *didn't* use the concept of developmental stages in relation to moral development. Rather, he differentiated two *types of moral orientation,* namely *heteronomous* and *autonomous* (see Table 35.1, page 607). Instead of seeing morality as a form of cognition, Piaget discussed morality in the context of affects and feelings (Eckensberger, 1999).

Understanding rules

To discover how moral knowledge and understanding change with age, Piaget began by looking at children's ideas about the rules of the game of marbles. He believed that the essence of morality lies in rules, and that marbles is a game in which children create and enforce their own rules free from adult influence. Piaget felt that in this way he could discover how children's moral knowledge in general develops. As he noted:

> Children's games constitute the most admirable social institutions. The game of marbles, for instance, as played by boys, contains an extremely complex system of rules ... that is to say, a code of laws, a jurisprudence of its own ... All morality consists in a system of rules.

Pretending he didn't know the rules, Piaget asked children to explain them to him and, during the course of a game, to tell him who made the rules, where they came from, and whether they could be changed. He found that children aged 5 – 9/10 tended to believe that the rules had always existed in their present form, and that they'd been created by older children, adults, or even God. The rules were sacred, and couldn't be changed in any way (an *external law*). Nevertheless, children unashamedly broke them to suit themselves, and saw nothing contradictory in the idea of both players winning the game.

Children aged 10 and above understood that the rules were invented by children themselves and could be changed, but only if all players agreed. The function of rules was to prevent quarrelling and ensure fair play. They adhered rigidly to the rules, and discussed the finer points and implications of any changes. Piaget called this moral orientation towards cooperation with peers *mutual respect,* which he distinguished from the *unilateral respect* shown by younger children towards adult authority.

According to Piaget, the rules of marbles could be used to study morality, since all morality consists of a system of rules

Moral judgement and punishment

Piaget also told children pairs of stories about (hypothetical) children who'd told lies, stolen or broken something.

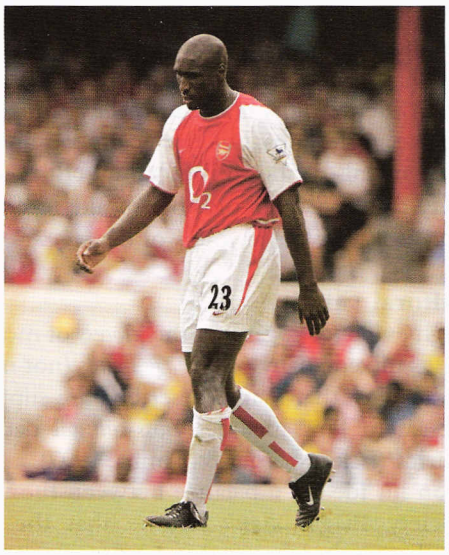
Box 35.2 Examples of pairs of stories used by Piaget

Example 1a: A little boy called John was in his room. He was called to dinner and went into the dining room. Behind the door there was a chair and on the chair there was a tray with 15 cups on it. John couldn't have known that the chair was behind the door, and as he entered the dining room, the door knocked against the tray and the tray fell on the floor, breaking all of the cups.

Example 1b: One day, a little boy called Henry tried to get some jam out of a cupboard when his mother was out. He climbed on to a chair and stretched out his arm. The jam was too high up, and he couldn't reach it. But while he was trying to get it, he knocked over a cup. The cup fell down and broke.

Example 2a: A little girl called Marie wanted to give her mother a nice surprise and so she cut out a piece of sewing for her. But she didn't know how to use the scissors properly and she cut a big hole in her dress.

Example 2b: A little girl called Margaret went and took her mother's scissors one day when her mother was out. She played with them for a bit and then, as she didn't know how to use them properly, she made a hole in her dress.



ASK YOURSELF...

- Piaget asked children who they believed was the naughtier and should therefore be punished more.
- Who do you think (a) 5–9/10 year olds and (b) children over 10 judged to be the naughtier?
- Why?

Piaget was more interested in the *reasons* children gave for their answers than the answers themselves. While 5–9/10-year-olds could distinguish an intentional act from an unintentional one, they tended to base their judgements on the severity of the outcome or the sheer amount of damage done. So, John and Marie were typically judged to be naughtier (*objective* or *external responsibility*).

By contrast, children aged 10 or above judged Henry and Margaret to be naughtier, because they were both doing something they shouldn't have been. Although the damage they caused was accidental, older children saw the motive or intention behind the act as being important in determining naughtiness (*internal responsibility*).

Regarding punishment, younger children believed that naughty people should pay for their crimes. In general, the greater the suffering the better, even though the form of punishment might be quite arbitrary. Such *expiatory* ('paying the penalty for') punishment is seen as decreed by authority and accepted as just because of its source

Sol Campbell of Arsenal being sent off. Did the whole team suffer for his moment of recklessness?

(*moral realism*). Thus, when a child in a class doesn't admit to a misdeed and the rest of the class doesn't identify the offender, young children see *collective punishment* (the whole class is punished) as being acceptable.

If someone who's been naughty and 'got away with it' suffers some misfortune, younger children often construed this as a punishment for the misdeed (*immanent justice*). For example, a child who lied but wasn't found out and later fell and broke his arm was being punished for the lie. God (or an equivalent force) is in league with those in authority to ensure that 'the guilty will always be caught in the end'.

By contrast, older children saw punishment as bringing home to the offender the nature of the offence, and as a deterrent to behaving wrongly in the future. They also believed that collective punishment was wrong, and that 'the punishment should fit the crime'. So, if one child stole another one's sweets, the offender must give his/her own sweets to the victim (based on the *principle of reciprocity*) or be punished in some other appropriate way. Older children no longer saw justice as being tied to authority (moral relativism), and there was less belief in immanent justice.

Box 35.3 Heteronomous and autonomous morality

- Piaget called the morality of young children *heteronomous* ('subject to another's laws or rules'). Older children possess *autonomous* morality ('subject to one's own laws or rules'), and see rules as the product of social agreements rather than sacred and unchangeable laws (the *morality of cooperation*).
- Piaget believed that the change from heteronomous to autonomous morality occurred because of the shift at about seven from egocentric to operational thought (see Chapter 34). This suggests that cognitive development is *necessary* for moral development, but since the latter lags at least two years behind the former, it cannot be *sufficient*.
- Another important factor is the change from *unilateral respect* (the child's unconditional obedience of parents and other adults) to *mutual respect* within the peer group (where disagreements between equals have to be negotiated and resolved).

An evaluation of Piaget's theory

- Piaget believed that popular girls' games (such as hopscotch) were too simple compared with boys' most popular game (marbles) to be worthy of investigation. While girls eventually achieve similar moral levels to boys, they're less concerned with legal elaborations. This apparent *gender bias* is also evident in Kohlberg's theory (see below).
- Piaget argued that *egocentrism* could be overcome via *social interaction* with *peers*. Intellectually, and in terms of status, adults are too far removed from children, but peers provide the ideal potential source of *sociological conflict* necessary for development to take place. It's

Table 35.1 Summary of Piaget's theory of moral development

	Understanding rules	Moral judgement and punishment
5–9/10-year-olds: **Heteronomous moral orientation** ('subject to another's laws or rules')	• *Rules represent an external law* • *Unilateral respect*	• *Objective/external responsibility* Belief in: • *expiatory punishment* • *moral realism* • *collective punishment* • *immanent justice*
10-year-olds and above: **Autonomous moral orientation** ('subject to one's own laws or rules')	*Mutual respect*	• *Internal responsibility* Belief in: • *principle of reciprocity* • *moral relativism* No longer believe in: • *collective punishment* • *immanent justice*

through resolution of conflict that cognitive development occurs (see Box 35.3), although there's no *logical* reason why it results in developmental advance (Bryant, 1990). Nevertheless, Piaget's claims have inspired some important research into the potential impact of peer interaction on *perspective-taking* (Davis, 2003: see Chapter 34).

According to Piaget, perspective-taking results partly from interactions with peers, especially when beliefs are challenged

Challenges to Piaget's claims regarding intention

- Children's understanding of intention is much more complex than Piaget believed, and children are able to bring this understanding to bear on moral decision-making. The pre-school child *isn't* amoral (Durkin, 1995).
- Piaget's stories make the *consequences* of behaviour explicit rather than the intentions behind it (Nelson, 1980). When three-year-olds see people bringing about negative consequences, they assume that their intentions are also negative. But when information about intentions is made explicit, even three-year-olds can make judgements about them, *regardless* of the consequences. This suggests they are only less proficient than older children at *discriminating* intentions from consequences, and in using these separate pieces of information to make moral judgements.
- Armsby (1971) found that 60 per cent of six-year-olds (compared with 90 per cent of ten-year-olds) judged the deliberate breaking of a cup as more deserving of punishment than accidental damage to a TV set. This suggests that at least some six-year-olds are capable of understanding intention in the sense of 'deliberate naughtiness', and that a small amount of deliberate damage is naughtier than a large amount of accidental damage.
- According to some information-processing theorists (e.g. Gelman & Baillargeon, 1983: see Chapter 34), aspects of development which Piaget attributed to the increasing complexity and quality of thought, are actually the result of an increasing capacity for the storage and retrieval of information. Most five-year-olds say that John is naughtier because he broke more cups than Henry. This is because they can remember who broke more cups, but they cannot remember all the other details of the stories. When efforts are made to rectify this, five-year-olds often take intention into account, *as well as* the amount of damage.

Cross-cultural validity

- Although evidence regarding the *process* of moral development is mixed, many of the *age trends* (not necessarily the actual ages) that Piaget described are supported by later research. This includes *cross-cultural* data, mainly from Africa (Eckensberger & Zimba, 1997).
- Based on his idea of a balance between the individual and society, Piaget *didn't* assume that the developmental changes he observed in his Swiss sample would necessarily be found in other cultures. On the contrary, he claimed that the essential issue was whether the cultural context would allow certain developmental changes to occur. This general orientation towards *contextualisation* is evident in current cross-cultural research (Eckensberger, 1999), and an interesting example is a study of lying and truth-telling by Lee *et al.* (1997).

CROSS-CULTURAL STUDY 35.2

Lying and truth-telling in China and Canada (Lee *et al.*, 1997)

- Lee *et al.* tested the claim that the understanding of lying is greatly influenced by the cultural norms and values in which individuals are socialised.
- 120 children from the People's Republic of China and 108 Canadian children (aged 7, 9 and 11) were compared. They were presented with four brief stories, two involving a child who intentionally carried out a good deed (valued by adults in both cultures) and two involving a child who carried out a bad deed (viewed negatively by adults in both cultures).
- When the story characters were questioned by a teacher as to who committed the act, they either lied or told the truth. The children were asked to evaluate the story characters' deeds and their verbal statements as either 'naughty' or 'good'.
- Overall, the Chinese children rated truth-telling *less* positively and lie-telling *more* positively in *prosocial settings* compared with the Canadian children.
- This indicates that the emphasis on self-effacement and modesty in Chinese culture overrides Chinese children's evaluations of lying in some situations.
- Both groups rated truth-telling *positively* and lie-telling *negatively* in *antisocial situations*, reflecting the emphasis in both cultures on distinguishing between misdeed and truth/lie-telling.

Lee *et al.*'s results suggest a close link between sociocultural practices and moral judgement in relation to lying and truth-telling. China is a communist–collectivist society, which values the community over the individual and promotes personal sacrifice for the social good. Admitting a good deed is viewed as a violation of both traditional Chinese cultural norms and communist–collectivist doctrine. By contrast, in western culture 'white lies' and deceptions to avoid embarrassment are tolerated, and concealing positive behaviour isn't explicitly encouraged (especially in the early school years).Although cognitive development plays an undeniable role (as argued by Kohlberg: see below), cultural and social factors are also key determinants in children's moral development (Lee *et al.*, 1997).

The People's Republic of China – a communist-collectivist society

Kohlberg's theory

As we noted earlier, Kohlberg's theory has dominated research in the field of moral reasoning for 30 years. Kohlberg was greatly influenced by Piaget, and, like him, believed that morality develops gradually during childhood and adolescence. Also like Piaget, he was more interested in people's *reasons* for their moral judgements than in the judgements themselves. For example, our reasons for upholding the law, as well as our views about whether there are circumstances in which breaking the law can be justified, might change as we develop.

Kohlberg assessed people's moral reasoning through the use of *moral dilemmas.* Typically, these involved a choice between two alternatives, both of which would be considered socially unacceptable. One of the most famous of these dilemmas concerns 'Heinz'.

ASK YOURSELF...

- Read Box 35.4 and try answering the questions about Heinz.

Box 35.4 An example of a moral dilemma

In Europe, a woman was near death from a special kind of cancer. There was one drug that the doctors thought might save her. It was a form of radium that a druggist in the same town had recently discovered. The drug was expensive to make, but the druggist was charging ten times what the drug cost him to make. He paid $400 for the radium and charged $4000 for a small dose of the drug. The sick woman's husband, Heinz, went to everyone he knew to borrow the money, but he could only get together about $2000, which was half of what the drug cost. He told the druggist that his wife was dying and asked him to sell it cheaper or let him pay later. But the druggist said, 'No, I discovered the drug and I'm going to make money from it.' So Heinz got desperate and considered breaking into the man's store to steal the drug for his wife.

1. Should Heinz steal the drug? (Why or why not?)
2. If Heinz doesn't love his wife, should he steal the drug for her? (Why or why not?)
3. Suppose the person dying isn't his wife but a stranger. Should Heinz steal the drug for the stranger? (Why or why not?)
4. (If you favour stealing the drug for a stranger.) Suppose it's a pet animal he loves. Should Heinz steal to save the pet animal? (Why or why not?)
5. Is it important for people to do everything they can to save another's life? (Why or why not?)
6. Is it against the law for Heinz to steal? Does that make it morally wrong? (Why or why not?)
7. Should people try to do everything they can to obey the law? (Why or why not?)
8. How does this apply to what Heinz should do?

(From Kohlberg, 1984)

ASK YOURSELF...

- In July 2004, a 100-year-old man, Bernard Heginbotham, who killed his 87-year-old wife by slitting her throat, avoided a prison sentence because the judge said he had acted out of love. Her health was failing and she'd been moved from one care home to another. He became very distressed and decided to end her suffering.
- Should he have killed his wife?
- Can slitting someone's throat be justified as an act of love?
- Should his age have been taken into account when passing sentence?
- Should he have been sent to prison?

Kohlberg's original study (beginning in 1956) involved 72 Chicago boys (10–16 years), 58 of whom were followed up at three-yearly intervals for 20 years (Kohlberg, 1984; Colby *et al.*, 1983; Colby & Kohlberg, 1987). Based on the answers given by this sample to the Heinz and other dilemmas, Kohlberg identified six qualitatively different stages of moral development, differing in complexity, with more complex types being used by older individuals. The six stages span three *levels* of moral reasoning:

1. at the *preconventional level,* we don't have a personal code of morality – instead, it's shaped by the standards of adults and the consequences of following or breaking their rules
2. at the *conventional level,* we begin to internalise the moral standards of valued adult role models
3. at the *postconventional level,* society's values (such as individual rights), the need for democratically determined rules and *reciprocity* (or *mutual action*) are affirmed (stage 5); in stage 6, individuals are guided by *universal ethical principles,* in which they do what their conscience dictates, even if this conflicts with society's rules.

Box 35.5 Kohlberg's three levels and six stages of moral development and their application to the Heinz dilemma

Level 1: Preconventional morality

Stage 1 (punishment and obedience orientation): What's right and wrong are determined by what is and isn't punishable. If stealing is wrong, it's because authority figures say so and will punish such behaviour. Moral behaviour is essentially the avoidance of punishment.

- Heinz *should* steal the drug. If he lets his wife die, he'd get into trouble.
- Heinz *shouldn't* steal the drug. He'd get caught and sent to prison.

Stage 2 (instrumental relativist orientation): What's right and wrong are determined by what brings rewards and what people want. Other people's needs and wants are important, but only in a reciprocal sense ('If you scratch my back, I'll scratch yours').

- Heinz *should* steal the drug. His wife needs it to live and he needs her companionship.
- Heinz *shouldn't* steal the drug. He might get caught and his wife would probably die before he got out of prison, so it wouldn't do much good.

Level 2: Conventional morality

Stage 3 (interpersonal concordance or 'good boy–nice girl' orientation): Moral behaviour is whatever pleases and helps others and doing what they approve of. Being moral is 'being a good person in your own eyes and the eyes of others'. What the majority thinks is right by definition.

- Heinz *should* steal the drug. Society expects a loving husband to help his wife regardless of the consequences.
- Heinz *shouldn't* steal the drug. He'll bring dishonour on his family and they'll be ashamed of him.

Stage 4 (maintaining the social order orientation): Being good means doing one's duty – showing respect for authority and maintaining the social order for its own sake. Concern for the common good goes beyond the stage 3 concern for one's family: society protects the rights of individuals, so society must be protected by the individual. Laws are unquestioningly accepted and obeyed.

- Heinz *should* steal the drug. If people like the druggist are allowed to get away with being greedy and selfish, society would eventually break down.
- Heinz *shouldn't* steal the drug. If people are allowed to take the law into their own hands, regardless of how justified an act might be, the social order would soon break down.

Level 3: Postconventional morality

Stage 5 (social contract–legalistic orientation): Since laws are established by mutual agreement, they can be changed by the same democratic process. Although laws and rules should be respected, since they protect individual rights as well as those of society as a whole, individual rights can sometimes supersede these laws if they become destructive or restrictive. Life is more 'sacred' than any legal principle, and so the law shouldn't be obeyed at all costs.

- Heinz *should* steal the drug. The law isn't set up to deal with circumstances in which obeying it would cost a human life.
- Heinz *shouldn't* steal the drug. Although he couldn't be blamed if he did steal it, even such extreme circumstances don't justify a person taking the law into his own hands. The ends don't always justify the means.

Stage 6 (universal ethical principles orientation): The ultimate judge of what's moral is a person's own conscience operating in accordance with certain universal principles. Society's rules are arbitrary and may be broken when they conflict with universal moral principles.

- Heinz *should* steal the drug. When a choice must be made between disobeying a law and saving a life, one must act in accordance with the higher principle of preserving and respecting life.
- Heinz *shouldn't* steal the drug. He must consider other people who need it just as much as his wife. By stealing the drug, he'd be acting in accordance with his own particular feelings with utter disregard for the values of all the lives involved.

(Based on Rest, 1983; Crooks & Stein, 1991)

Charles Bronson in *Death Wish*: taking the law into his own hands in the most extreme way possible

KEY STUDY 35.1 Distributive justice (Damon, 1977)

- A typical *distributive justice* task involved children being asked to imagine that there's a school in desperate need of funds to buy essential writing materials (pens and notebooks). Teachers organise an open day and fair to raise funds.
- The art teacher asks the class to paint pictures for sale, the open day is a great success and more money is raised than needed. The teacher is given some of the surplus money, and the critical question is: *How does she distribute the money to the children?*
- The three possibilities are: *equality* (each child receives the same amount); *need (poorer* children receive more); and *merit* (those who worked hardest or whose paintings sold best are given more).
- Even four-year-olds recognise the importance of sharing, and eight-year-olds can appreciate and discuss all three ways of sharing the money.

Both Piaget and Kohlberg saw cognitive development as necessary for, and setting a limit on, the maturity of moral reasoning, with the latter usually lagging behind the former. So, for example, formal operational thought (see Chapter 34) is needed to achieve stages 5 and 6, but it cannot *guarantee* it. Because formal operational thought is achieved by a relatively small proportion of people, it's hardly surprising that only about 15 per cent of adults attain stages 5 and 6 (Colby *et al.*, 1983 see Table 35.1).

An evaluation of Kohlberg's theory

- Research has shown that young children's understanding of moral regulation is much more sophisticated than implied by Kohleberg's Stage 1 (Hart *et al.*, 2003). Damon (1977) was one of the first to demonstrate that Stage 1 children reason in thoughtful ways about sharing in peer contexts. Children have considerable experience of sharing food and toys with friends, which is translated into implicit principles. But they have little experience with the kinds of issues raised by Kohlberg's dilemmas. So, their reasoning about theft and the importance of human life is rather muddled. Their moral understanding is, however, much more complex and sophisticated than was believed 30 years ago (Hart *et al.*, 2003).
- Findings from Kohlberg's longitudinal study showed that those who were initially at low stages had advanced to higher stages, suggesting 'moral progression' (Colby *et al.*, 1983). Based on these findings, he argued that the first five stages are *universal,* and that they occur in an *invariant sequence.* Similarly, Rest's (1983) 20-year longitudinal study of men from adolescence to their mid-thirties showed that the

Table 35.2 The relationship between Kohlberg's stages and Piaget's types of moral development, and Piaget's stages of cognitive development

Kohlberg's levels of moral development	Age group included within Kohlberg's developmental levels	Corresponding type of morality (Piaget)	Corresponding stage of cognitive development (Piaget)
Preconventional (stages 1 and 2)	Most 9-year-olds and below. Some over nine	Heteronomous (5–9/10)	Pre-operational (2–7)
Conventional (stages 3 and 4)	Most adolescents and adults	Heteronomous (e.g. respect for the law/authority figures) plus autonomous (e.g. taking intentions into account)	Concrete operational (7–11)
Postconventional (stages 5 and 6)	10–15% of adults, not before mid-30s	Autonomous (10 and above)	Formal operational (11 and above)

developmental stages seem to occur in the order described by Kohlberg.

Is it culturally biased?

- According to Snarey's (1987) review of 45 studies conducted in 27 different cultures, the data 'provide striking support for the universality of Kohlberg's first four stages'. However, Kohlberg & Nisan (1987) studied Turkish youngsters, both from a rural village and a city, over a 12-year period. Their scores overall were lower than Americans', and rural youngsters scored lower than the urban dwellers. Snarey *et al.* (1985) reported that Israeli youngsters (aged 12–24) educated in kibbutzim scored *higher* than Americans at all ages.

These findings suggest that cultural factors play a significant part in moral reasoning. According to the *sociocultural approach,* what 'develops' is the individual's skill in managing the moral expectations of one's culture, expressed through linguistic and symbolic practices. This contrasts sharply with Kohlberg's cognitive–developmental model, which concentrates on individual processes 'inside the head' (Haste *et al.*, 1998).

CROSS-CULTURAL STUDY 35.3

Cultural bias in Kohlberg's theory

- Stage-6 reasoning is based on supposedly 'universal' ethical principles, such as *justice* (which is central to Kohlberg's theory), *equality, integrity,* and *reverence for life*. However, these *aren't* universally held (Shweder, 1991; Eckensberger, 1994).
- For example, South East Asian culture places *family loyalty* at the centre of its ethical system. Shweder *et al.* (1987) gave the Heinz dilemma to people living in Indian Hindu villages. One very morally sophisticated reasoner reached very different conclusions, supported by very different arguments, from that expected in western culture. He was clearly using a high stage of reasoning, but it was impossible to score him on the Kohlberg measure, because his arguments were too far removed from the western position (Shweder, 1990).
- Indian adolescents and adults made frequent reference to notions of *the divine* in their moral justifications, as opposed to the western notion of justice (Shweder *et al.*, 1997).
- Iwasa (1992) compared Americans and Japanese using the Heinz dilemma. There was no difference in the overall level of moral development, but there were qualitative differences in *why* human life was valued, reflecting cultural norms. While Americans were concerned to prolong length of life, the Japanese were concerned to make it purer and cleaner. Hence, most Americans thought Heinz should steal, while most Japanese thought he shouldn't.

- Eckensberger (1999) maintains that Kohlberg's theory isn't as 'western based' as some critics have claimed. For example, the highest stages can be found in India, Taiwan, and Israel. It appears to be the degree of 'complexity' (industrialisation) – and not 'westernisation' – that assists the development to higher stages.

Nevertheless, cultural psychologists believe that instead of looking for universal moral stages, we should be trying to understand moral *diversity.* A focus on justice may be very far from some cultures' primary ethical concerns:

> If the researchers try to measure justice reasoning, rather than eliciting people's usual moral framework, stage scores may be misleading, but more importantly, the results would fail to give a true picture of people's moral lives ... (Haste *et al.*, 1998)

Is it gender biased?

- The claim that Kohlberg's theory is biased towards western cultural ideals (*Eurocentrism*) mirrors a second major criticism, namely that it's biased in favour of males (*androcentrism:* see Chapter 47). Gilligan (1982, 1993) has argued that because Kohlberg's theory was based on an all-male sample, the stages reflect a male definition of morality.

ASK YOURSELF...

- What do you think Gilligan might mean by a 'male definition of morality'?
- How might this differ from a female definition of morality?

- While men's morality is based on abstract principles of law and justice, women's is based on principles of compassion and care. In turn, the different 'moral orientations' of men and women rest on a deeper issue, namely how we think about *selfhood.* An ethic of justice (male) is a natural outcome of thinking of people as separate beings, in continual conflict with each other, who make rules and contracts as a way of handling that conflict. A 'female' ethic of caring/responsibility follows from regarding selves as being in connection with one another.
- However, the claim that women 'think differently' about moral issues has been challenged. According to Johnston (1988), each sex is competent in each mode, but there are gender-linked preferences. While boys tended to use a justice orientation, if pressed they'd also use the care orientation. Similarly, girls preferred a care orientation, but also switched easily. According to Haste *et al.* (1998), these findings support Gilligan's argument that there's more than one moral 'voice', but *not* her claim that the 'caring' voice was more apparent amongst women. Several studies show that sex differences in moral orientations

are less important than the kind of dilemmas being considered.

KEY STUDY 35.2 Are males and females morally different? (Walker, 1989)

- Walker studied a large sample of males and females, aged 5–63. Participants were scored for both moral stage and orientation on both *hypothetical* and *personally generated, real-life dilemmas*. The only evidence of sex differences was for adults on real-life dilemmas.
- When asked to produce real-life dilemmas, females reported more *relational/personal* ones and males reported more *non-relational/impersonal* dilemmas (Walker *et al.*, 1987). A relational/personal conflict involves someone with whom the participant has a significant and continuing relationship (e.g. whether or not to tell a friend her husband was having an affair). A non-relational/impersonal conflict involves acquaintances or strangers (e.g. whether or not to correct a shop assistant's error in giving too much change).
- Regardless of gender, *personal/relational* dilemmas produced a higher level of response than impersonal/non-relational dilemmas. This is the *opposite* of what Gilligan claimed, namely that Kohlberg's stages are biased against an ethic of care (Walker, 1996).
- Both males and females tended to use the ethic of care mostly in personal dilemmas, and most people used both orientations to a significant degree, with no clear focus or preference. According to Walker (1996), the nature of the dilemma is a better predictor of moral orientation than is gender.
- Walker (1984, 1995) also refuted Gilligan's claim that Kohlberg's scoring system was biased against females, making them more likely to be rated at the conventional level, and men at the post-conventional level. Based on a review of all the available research evidence relating to gender differences (80 studies, 152 distinct samples, and over 10,000 participants), he found that, regardless of age category, the typical pattern was one of non-significant differences. Once any educational or occupational differences favouring men were controlled for, there was no evidence of a systematic sex difference in moral stage scores.

◎ The higher stages in Kohlberg's theory are associated with education and verbal ability (Shweder *et al.*, 1987). While 'college-educated' people give higher-level and more mature explanations of moral decisions, this doesn't make them more moral than the non-college-educated. The former might simply be more sophisticated verbally. Nor is postconventional morality necessarily superior to conventional morality (Shweder, 1991), and even Kohlberg (1978) acknowledges that there may not be a separate sixth stage.

ASK YOURSELF...

- Do you always/necessarily act in accordance with your moral principles/beliefs?
- If not, can you account for the inconsistency?

CRITICAL DISCUSSION 35.2 How are moral reasoning and moral behaviour related?

- Moral reasoning and moral behaviour aren't necessarily correlated (Gibbs & Schnell, 1985). While moral reasoning may determine moral talk, 'talk is cheap' (Blasi, 1980), and what we say and what we do when faced with a moral dilemma often differ, particularly under strong social pressure. Moral development research should really look at what people *do*, rather than what they *say they'd do* (Mischel & Mischel, 1976).
- People may give one moral justification but act on another (Carlsmith *et al.*, 2002). For example, when people are asked to justify punishment by society (as in the criminal justice system), they often cite *utilitarian* motives (such as *deterrence*) that aim to prevent further harm-doing. But, in practice, people make choices that reflect *revenge* and *retribution* (criminals should 'get what's coming to them'). According to Fiske (2004):

  ... Their decisions about penalties do not reflect their high-minded ideals about the operations of society, but rather punishment in proportion to harm, or ... the criminal's apparent 'internal wickedness'.

Again:

People's lack of moral self-insight suggests that moral reasoning may be a post-hoc rationale, rather than a true underlying motive ...

In other words, moral judgements may be a way of trying to defend or justify our moral actions *after the event*, and there's growing evidence suggesting that moral responses are relatively automatic, and much more emotional and intuitive than rational and abstract (Fiske, 2004).

- The relationship between moral judgement and action is extremely complex and poorly understood. Although those who reason at a higher stage are more likely to act prosocially than those at lower stages, the relationship is weak. This is hardly surprising, however, given that behaviour is *multiply determined* (influenced by both psychological and external factors) (Hart *et al.*, 2003). No single factor, such as moral stage, can be expected to direct behaviour. As Blasi (1980) says, moral stages represent ways of thinking about moral issues, *not* specific behavioural tendencies. Two people at the *same* stage may reach *different* judgements; conversely, two people at *different* stages can choose the *same* course of action – but for *different reasons*.

Angry crowd jeering at a criminal en route to his trial

Eisenberg's theory of prosocial moral reasoning

Kohlberg's concept of moral reasoning is *prohibition-oriented*. In the case of Heinz, for example, one prohibition (stealing) is pitted against another (allowing his wife to die). But not all 'moral conflicts' are like this. Eisenberg (1982, 1986; Eisenberg *et al.*, 1991) argues that if we want to understand developmental changes in helping or altruism (see Chapter 30), we need to examine children's reasoning when faced with a conflict between their own needs and those of others, in a context where the role of laws, rules, and the dictates of authority are minimal. This describes *prosocial moral reasoning*.

In a series of studies during the 1980s, Eisenberg presented children of different ages (sometimes followed up into early adulthood) with illustrated hypothetical stories, in which the character can help another person, but at a personal cost.

Box 35.6 A hypothetical story used by Eisenberg to assess prosocial reasoning

A girl named Mary is going to a friend's birthday party. On her way, she sees a girl who has fallen down and hurt her leg. The girl asks Mary to go to her home and get her parents so the parents can take her to the doctor. But if Mary does run and get the child's parents, she will be late for the birthday party and miss the ice cream, cake and all the games.

What should Mary do? Why?

Based on children's responses to this and other similar dilemmas, Eisenberg identified six stages of prosocial moral reasoning.

Table 35.3 Stages of prosocial moral reasoning (based on Eisenberg, 1982, 1986)

Level 1 (hedonistic, self-focused orientation): The individual is concerned with selfish, pragmatic consequences, rather than moral considerations. For example, 'She shouldn't help, because she might miss the party'. What's 'right' is whatever is instrumental in achieving the actor's own ends/desires. Reasons for helping/not helping include direct gain for the self, expectations of future reciprocity, and concern for others whom the individual needs and/or likes.

[This is the predominant mode for preschoolers and younger primary-schoolers.]

Level 2 (needs of others orientation): The individual expresses concern for the physical, material and psychological needs of others, even though these conflict with his/her own needs. For example, 'She should help, because the girl's leg is bleeding and she needs to go to the doctor'. This concern is expressed in the simplest terms, without clear evidence of self-reflective role-taking, verbal expressions of sympathy, or reference to internalised affect, such as guilt.

[This is the predominant mode for many preschoolers and primary-schoolers.]

Level 3 (approval and interpersonal orientation and/or stereotyped orientation): Stereotyped images of good and bad persons and behaviours and/or considerations of others' approval/acceptance are used in justifying prosocial or non-helping behaviours. For example, 'It's nice to help' or 'Her family would think she did the right thing'.

[This is the predominant mode for some primary-schoolers and secondary-school students.]

Level 4a (self-reflective empathic orientation): The individual's judgements include evidence of self-reflective sympathetic responding, role-taking, concern with others' humanness, and/or guilt or positive affect related to the consequences of one's actions. For example, 'She cares about people', and 'She'd feel bad if she didn't help because she'd be in pain'.

[This is the predominant mode for a few older primary-schoolers and many secondary-school students].

Level 4b (transitional level): The individual's justifications for helping/not helping involve internalised values, norms, duties or responsibilities, or refer to the need to protect the rights and dignity of others. But these aren't clearly or strongly stated. For example, 'It's just something she's learnt and feels'.

[This is the predominant mode for a minority of people of secondary-school age and older.]

Level 5 (strongly internalised stage): As for 4b, but internalised values, norms etc are much more strongly stated. Additional justifications for helping include the desire to honour individual and societal contractual obligations, improve the conditions of society, and belief in the dignity, rights and equality of all human beings. It's also characterised by the wish to maintain self-respect for living up to one's own values and accepted norms. For example, 'She'd feel bad if she didn't help because she'd know she didn't live up to her values'.

[This is the predominant mode for a very small minority of secondary-school students and no primary-schoolers.]

An evaluation of Eisenberg's theory

- In a review of her research, Eisenberg (1996) points out that, as predicted, children almost never said they'd help in order to avoid punishment or because of blind obedience to authority, such as adults. This would be expected, given that children are seldom punished for not acting in a prosocial way (but *are* often punished for wrongdoing). This differs greatly from what's been found for prohibition-oriented moral reasoning.
- For Kohlberg, other-oriented reasoning emerges relatively late, but Eisenberg expected to find it by the pre-school years. Even four- to five-year-olds often appeared to orient to others' needs, showing what seemed to be primitive empathy. Also, references to empathy-related processes (such as taking the other's perspective and sympathising) are particularly common in prosocial moral reasoning.
- Contrary to Kohlberg's claims, even individuals who typically used higher-level reasoning occasionally reverted to lower-level reasoning (such as egotistic, hedonistic reasoning). This was especially likely when they chose not to help, suggesting the influence of *situational variables.* These are also implicated by some cross-cultural studies. For example, children raised on Israeli kibbutzim are especially likely to emphasise reciprocity between people, whereas city children (Israeli and from the USA) are more likely to be concerned with personal costs for helping others. If individuals' moral reasoning can vary across situations, then there's likely to be only a modest relationship between their typical level of moral reasoning and their actual prosocial behaviour. This is supported by Eisenberg's research (see Critical Discussion 35.2).
- One additional factor that's been implicated is emotion, in particular, *empathy.* Whether or not children help others depends on the *type* of emotional response that others' distress induces in them (rather than *whether or not* they respond emotionally). People who respond *sympathetically/empathically* (associated with, for instance, lowered heart rate) are more likely to help than those who experience *personal distress* (associated with accelerated heart rate).

ASK YOURSELF...

- How are these findings related to the *empathy–altruism hypothesis* and *universal egoism* discussed in Chapter 30?

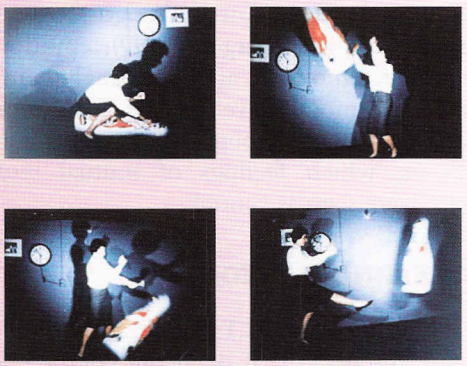
- A fundamental assumption of the *arousal: cost reward* (ACR) *model* of helping behaviour is that people are emotionally responsive to others' distress. Both adults and children not only report feeling empathy, they also become physiologically aroused by others' distress. Preschoolers also spontaneously show signs of facial concern and physiological arousal (Fabes *et al.*, 1993), and even one- to two-*day*-olds cry in response to another baby's distress (Sagi & Hoffman, 1976).
- There's a clear relationship between emotional regulation in parents and in their children, with sympathetic parents having sympathetic children (Eisenberg *et al.*, 1991). Democratic, warm and reasoning parenting is associated with an increased capacity for children's prosocial behaviour. Not surprisingly, autocratic, cold, harsh and inconsistent parenting predicts children's antisocial tendencies (Coie & Dodge, 1998).
- According to Eckensberger (1999), emotions (especially positive emotions) are increasingly being seen as the basis for moral development. This represents a move away from Kohlberg's theory and a return to Piaget's, in which feelings of mutual respect and empathy were seen as central.

SOCIAL LEARNING THEORY

Social learning theories (SLTs), such as those of Bandura (1977a) and Mischel (1973), originated in the USA in the 1940s and 1950s. They were an attempt to reinterpret certain aspects of Freud's psychoanalytic theory in terms of *learning theory* (classical and operant conditioning: see Chapter 11). In the 1960s and 1970s, Bandura and his colleagues tried to make Freud's concept of identification more objective by studying it experimentally in the form of *imitation.*

More specifically, many of these experiments were concerned with aggression (see Key Study 35.2). SLT has also been applied to many aspects of development, such as gender (see Chapter 36) and morality. This focus on *human social behaviour* is one feature that sets SLT apart from conditioning (or orthodox learning) theory.

Some important similarities and differences between SLT and orthodox learning theory



- While SL theorists agree that all behaviour is learned according to the same learning principles, they're interested specifically in *human learning.*
- Although SL theorists agree that we should observe what's observable, they also believe that there are important *cognitive mediating variables* which intervene between stimulus and response, without which we cannot adequately explain human behaviour (see Box 35.7, page 617).
- SL theorists emphasise *observational learning* or *modelling* (learning through watching the behaviour of others, called *models*). This occurs spontaneously, with no deliberate effort by the learner, or any intention by the model to teach anything.

Observational learning takes place without any reinforcement – mere exposure to the model is sufficient for learning to occur (Bandura, 1965). However, whether the model's behaviour is imitated depends partly on the

consequences of the behaviour, for both the model and the learner. Reinforcement is important only in so far as it affects *performance* (not the learning itself).

KEY STUDY 35.3 Learning versus performance (Bandura, 1965)

- Bandura (1965) showed three groups of children a film of an adult behaving aggressively towards a *Bobo doll*.

Group A (control) saw the adult kicking, pummelling and punching the Bobo doll.

Group B (model-rewarded) saw what group A saw, but a second adult appeared towards the end of the film and commended the model's aggressive behaviour. Sweets and lemonade were offered to the model.

Group C (model-punished) also saw the same filmed aggression, but this time a second adult scolded the model and warned against further aggression.

- So, the only difference between the three groups was the *consequences for the model* of his/her aggression.
- After the film, all the children (individually) went into a playroom, which contained a large number of toys, including a Bobo doll and a mallet. They were observed for 10 minutes, and the number of acts of *imitative aggression* was recorded for each child.
- While group C children showed *significantly fewer* aggressive acts than groups A and B, there was no difference between these two groups. This suggests that *vicarious punishment* is more powerful than *vicarious reinforcement*.
- More importantly, all the children were later asked to reproduce as much of the model's behaviour as they could, and were directly rewarded for each act of imitative aggression. Under these conditions, all three groups showed the *same* high levels of imitative aggression.

ASK YOURSELF...

- What do these findings tell us about what children in the different groups learned when originally observing the model?

- This shows that group C children must have attended to and remembered the model's behaviour (*learned* from the model) to the same extent as those in groups A and B. But this learning hadn't been apparent in their *performance* when they were first observed, but only after receiving direct reinforcement. Hence, reinforcement (either vicarious or direct) wasn't needed for learning (acquisition), but it was for imitation (performance).

After watching a film of an aggressive model who punched, kicked and hurled a Bobo doll, these children spontaneously imitated the model's aggression

Reinforcement as information about the future

Bandura (1977a) challenged Skinner's claim that reinforcements and punishments automatically strengthen and weaken behaviour (see Chapter 11). For Bandura:

> Reinforcement serves principally as an informative and motivational operation rather than as a mechanical response strengthener.

Reinforcement provides the learner with *information* about the likely consequences of certain behaviour under certain conditions: it improves our prediction of whether a given action will lead to pleasant (reinforcement) or unpleasant (punishment) outcomes in the *future*. It also *motivates* us by causing us to anticipate future outcomes. Our present behaviours are largely governed by the outcomes we expect them to have, and we're more likely to try to learn the modelled behaviour if we value its consequences.

The role of cognitive factors in observational learning

The learning process is much more complex for Bandura than it is for Skinner, for whom 'the mind' had no part to play in a scientific psychology (see Chapter 2). In Bandura's (1974) view:

> Contrary to mechanistic metaphors, outcomes change behaviour in humans through the intervening influence of thought.

Box 35.7 Five cognitive mediating variables influencing the likelihood of learning and/or performance

- The learner must *pay attention to* the relevant clues and ignore those aspects of the model and the environment that are incidental and irrelevant. Attention can be influenced by the model's distinctiveness, attractiveness, or power (whether or not the model's behaviour has functional value for the learner), the learner's level of arousal, and expectations about the model.
- A *visual image* or *semantic code* for the modelled behaviour is recorded in memory. Without an adequate coding system, the learner will fail to store what's been seen or heard (see Chapter 17). While infants are largely confined to immediate imitation, older children can defer imitation because of their superior use of symbols (see Chapter 34).
- *Memory permanence* derives from the use of devices such as rehearsal and organisation, and employing multiple codes to help retain the stored information over long periods.
- *Reproducing the observed motor activities* accurately usually requires several trials to get the muscular 'feel' of the behaviour. Older children enjoy greater muscular strength and control.
- *Motivation* refers to the role of reinforcement, which can be direct (as when the child is praised by an adult), or vicarious (as when a child sees another child being praised: see Key Study 35.3) *Self-reinforcement* is also possible (as when the child praises itself/feels pleased with itself).

An evaluation of Bandura's SLT

Is SLT a developmental theory?

- As noted in Box 35.7, changes take place in cognitive or mediating processes as children get older. However, these processes essentially apply at any age, which means that the theory isn't a true theory of development (Durkin, 1995).
- Bandura resists the notion of a general structural reorganisation of the kind proposed by Piaget (see Chapter 34), and so he fails to take account of cognitive *development* (Grusec, 1992). As Bee (2000) points out, SLT can say how a child might acquire a particular behaviour pattern, but it doesn't take into account the underlying developmental changes that are occurring. For example, do three-year-olds and ten-year-olds typically learn the same amount or in the same way from modelling? As Bee (2000) notes:

> Given Bandura's emphasis on cognitive aspects of the modelling process, a genuinely developmental social learning theory could be proposed, although no such theory now exists.

Indeed, the importance of cognitive factors is reflected in Bandura's (1986, 1989) renaming of SLT as *social cognitive theory* (SCT). Other important cognitive processes are those relating to the self.

Box 35.8 Self-concept, self-monitoring, and self-efficacy

- According to Bandura, children learn both overt behaviour/concrete skills and information, and also abstract skills and information through modelling. Indeed, *abstract modelling* is part of his SCT (1986, 1989). For example, the 'rule' underlying a model's behaviour can be extracted from observing the behaviour, without the rule being made explicit or articulated. In this way, the child can acquire attitudes, values, expectancies, ways of solving problems, and standards of self-evaluation.
- By incorporating (or internalising) societal standards into its self, the child can monitor its own behaviours in terms of these standards. This *self-monitoring* ensures that behaviour is regulated even in the absence of reinforcement. Indeed, according to Bandura (1971), 'There is no more devastating punishment than self-contempt'; that is, we are our own harshest critics. This mirrors Freud's view of the young child's superego, which is often more punitive than the parents it has replaced (see page 603).
- Another internalised standard or expectancy is *self-efficacy*. This refers to our belief that we can act effectively and exercise some control over events that influence our lives (Bandura, 1977a, 1986). This is crucially important for motivation, since how we judge our own capabilities is likely to affect our expectations about future behaviour. For example, if we feel that a model's actions are within our capabilities, then we may attempt to imitate them, but a low sense of self-efficacy regarding the modelled skill is likely to inhibit us (Durkin, 1995).

- One of the strengths of Bandura's SLT (and other versions, such as that of Mischel, 1973) is the claim that behaviour can be understood only by taking the actor's self-concept, self-monitoring, self-efficacy, and other mediating variables into account. However, these internal processes don't constitute 'personality', a concept which most SL theorists tend to dismiss (Durkin, 1995: see Chapter 42). Nevertheless, they make the theory far less mechanistic than Skinner's, for example, which focuses entirely on external events. For Bandura (1973):

The environment is only a potentiality, not a fixed property that inevitably impinges upon individuals and to which their behaviour eventually adapts. Behaviour partly creates the environment and the resultant environment, in turn, influences the behaviour.

This view is called *reciprocal determinism* (Bandura, 1977a, 1986). People are both products and producers of their environments.

CONCLUSIONS

As we noted in the *Introduction and overview,* different psychological theories attempt to answer quite different questions about moral development. To the extent that all these questions are relevant to understanding the full complexity of moral development, psychoanalytic theory, cognitive developmental theories, and SLT all make significant contribution to our understanding of this critically important aspect of socialisation.

CHAPTER SUMMARY

- According to Freud, the **psychic apparatus** consists of the **id**, **ego** and **superego**. The id and the ego are governed by the **pleasure principle** and **reality principle** respectively. The superego comprises the **conscience** and **ego-ideal**, representing the **punishing** and **rewarding** parent respectively.
- A boy's **Oedipus complex** ends when he identifies with his father (**identification with the aggressor**), motivated by his **fear of castration/castration anxiety**. Since a girl's Oedipus complex begins with her belief that she's already been castrated, Freud found it difficult to explain her identification with her mother. One suggestion was **anaclitic identification**.
- There's no evidence to support Freud's claim that females have weaker superegos than males, and **penis envy** has been reinterpreted as envy of men's superior social status.
- **Cognitive–developmental theories** are concerned with the **reasons** underlying moral judgements, rather than the judgements themselves.
- According to Piaget, the change from **heteronomous** to **autonomous** morality occurs due to the shifts from egocentric to operational thought, and from **unilateral respect** and adult constraint to **mutual respect** within the peer group.
- Although children's understanding of **intention** is much more complex than Piaget believed, many of the age trends he described have been supported by cross-cultural studies, mainly from Africa.
- Kohlberg identified six qualitatively different **stages** in moral development, spanning three basic levels of moral reasoning: **preconventional**, **conventional** and **postconventional morality**.
- Despite extensive empirical support for the sequence and universality of the (first four) stages, the **sociocultural approach** maintains that cultural factors play a significant part in moral reasoning. For Kohlberg, the focus is on what takes place within the individual's head.
- Kohlberg's theory has been criticised for its bias towards **western** cultures, and for being based on a **male** definition of morality. However, several studies show that gender differences in morality are less important than the **kind of dilemmas** being considered.
- Kohlberg has also been criticised for overemphasising moral **thinking** (rather than behaviour), and those who attain the highest stages may simply be more sophisticated verbally. A separate stage 6 may not even exist.
- While Kohlberg's theory is **prohibition-oriented**, Eisenberg concentrates on the development of **prosocial moral reasoning**. Many of the predictions derived from her theory have been supported, and her research has also indicated that **situational variables** influence moral reasoning.
- **Empathy**, and other positive emotions, are becoming increasingly important in explanations of moral development.
- Bandura's **social learning theory** (SLT) investigated Freud's concept of identification, largely through laboratory experiments of **imitative aggression**.
- Bandura emphasised **observational learning/modelling**, distinguished between **learning** and **performance**, and identified several **cognitive variables** that **mediate** between observation of a model's behaviour and its imitation.
- **Reinforcement** is a source of both **information** and **motivation**. While not necessary for learning, reinforcement (direct, vicarious or self-administered) may be needed for **performance**.
- **Self-reinforcement** is related to **self-monitoring**, the SLT equivalent of Freud's superego. This represents an internalised societal standard or expectancy, another example being **self-efficacy**.

Links with other topics/chapters

- Through the concept of fixation, Freud was able to explain how *individual differences in personality* arise from common developmental patterns (Chapter 42).
- The concept of maturation relates to the *nativist* explanation of behaviour. Like Piaget (Chapter 34), Freud saw both biological and *experiential* factors contributing to personality development, especially individual differences (Chapter 50).
- *Feminist psychologists* have criticised the *androcentric* (male-centred) *nature* of Freud's and Kohleberg's theories (Chapter 47).
- Taking credit for good deeds (part of the *self-serving bias:* Chapter 23) is an accepted part of self-promotion (trying to create a favourable impression in others –

impression management: Chapter 22) in western *individualist* cultures, while in China (and other *collectivist* cultures) it's seen as a character flaw (Chapter 47).

- *Cross-cultural* studies of, say, Kohlberg's theory, are more likely to look for the *universal* nature of the stages, while *cultural psychologists* are interested in *cultural diversity* (Chapter 47).
- Gilligan's distinction between male and female moralities could be seen as the gender equivalent of the distinction between *individualist* and *collectivist cultures* (Chapter 47).
- The inconsistency between what people say and what they believe is demonstrated in Asch's *conformity experiments* (Chapter 26). The inconsistency between what people say they'd do and what they'd probably do under particular conditions is demonstrated in studies of *obedience* (Chapter 27).
- An inability to feel empathy for others may help explain (some cases of) *criminal behaviour* (Chapter 46), as can the lack of guilt associated with *affectionless psychopathy* (Chapter 32).
- Bandura's study of observational learning in relation to *imitation of aggression* represented the first wave of research into the effects of *media violence* (Chapter 29).
- Bandura's concept of self-efficacy is important for understanding and evaluating the effects of all forms of *psychotherapy* (Chapter 45).
- Reciprocal determinism is relevant to the debates concerning *free will and determinism* (Chapter 49) and *nature–nurture* (Chapter 50).

GENDER DEVELOPMENT

INTRODUCTION AND OVERVIEW

Often the first thing we notice about other people is whether they're male or female. The importance of *sexual identity* to our self-concept and our interactions with others is a reflection of the fact that every known culture distinguishes between male and female (see Chapter 33). In turn, this distinction is accompanied by widely and deeply held beliefs (*stereotypes*) about the psychological make-up and behaviours belonging to each sex (see Chapter 22). The study of *psychological sex differences* is really an attempt to see how accurate these stereotypes are.

At the beginning of the twentieth century (especially in the USA), many of the first generation of scientifically trained women psychologists channelled their research efforts into the extent and nature of sex differences. But psychology's interest in this research area waned with the rise of behaviourism (Crawford & Unger, 1995). Interest was revived in the 1970s, driven largely by *feminist psychologists*. According to feminist interpretations of sex differences, social, political, economic, and cultural factors determine *gender*, our awareness and understanding of the differences that distinguish males from females. This view is directly opposed to those of *sociobiologists* and *evolutionary psychologists*, who argue that sex differences are 'natural', having evolved as a part of the more general adaptation of the human species to its environment (see Chapter 2 and Clamp, 2001).

Other theoretical accounts of gender and gender differences include *biological approaches, biosocial theory, psychoanalytic theory, social learning theory, cognitive–developmental theory,* and *gender schema theory.* All of these, with the exception of biological approaches, stress the *interaction* between biological and environmental influences, albeit in quite different ways.

THE 'VOCABULARY' OF SEX AND GENDER

ASK YOURSELF...
- Excluding the act of sex (or sexual behaviour), can 'sex' mean different things?
- What's the difference between 'sex' and 'gender'?

Feminist psychologists (e.g. Unger, 1979) distinguish between sex and gender. Sex refers to the biological facts about us, such as genetic make-up, reproductive anatomy and functioning, and is usually referred to by the terms 'male' and 'female'. Gender, by contrast, is what culture makes out of the 'raw material' of biological sex. It's the *social equivalent* or *social interpretation* of sex.

Sexual identity is an alternative way of referring to our biological status as male or female. Corresponding to gender is *gender identity,* our classification of ourselves (and others) as male or female, boy or girl, and so on. Sexual and gender identities correspond for most people, but not in *transsexualism*. While being anatomically male or female, transsexuals firmly believe that they belong to the opposite sex. As a result, their biological sexual identity is fundamentally inconsistent with their gender identity.

Gender role (or *sex role*) refers to the behaviours, attitudes, values, beliefs and so on which a particular society either expects from, or considers appropriate to, males and females on the basis of their biological sex. To be *masculine* or *feminine,* then, requires males or females to conform to their respective gender roles.

Nadia Almada, the Portuguese transsexual winner of *Big Brother* 2004

All societies have carefully defined gender roles, although their precise details differ between societies. *Gender* (or sex) *stereotypes* are widely held beliefs about psychological differences between males and females which often reflect gender roles (see pages 624-625).

Sex typing is the process by which children acquire a sex or gender identity and learn gender-appropriate behaviours (adopt an appropriate sex role). Sex typing begins early in western culture, with parents often dressing their new-born baby boy or girl in blue or pink. Even in the earliest days of infancy, our gender influences how people react to us (Condry & Ross, 1985). Indeed, usually the first question asked by friends and relatives of parents with a new-born baby is 'Boy or girl?'. By age three or four, most children have some knowledge about their own genders. They know, for example, that boys become men and girls become women, and that some games are played by boys and others by girls. A permanent gender identity is usually acquired by age five (see Box 36.4, page 630).

BIOLOGY AND SEXUAL IDENTITY

Biologically, sex is a *multidimensional* variable, and there are at least five categories of biological factors that influence gender identity.

Box 36.1 Five categories of biological sex

Chromosomal sex: Normal females inherit two X chromosomes, one from each parent (XX). Normal males inherit one X chromosome from the mother and one Y chromosome from the father (XY). Two chromosomes are needed for the complete development of both internal and external female structures, and the Y chromosome must be present

for the complete development of male internal and external structures (Page *et al.*, 1987). For many years it was believed that if the Y chromosome were absent, female external genitals would develop. However, a *female-determining gene* has been located on the X chromosome (Unger & Crawford, 1996). Female embryos begin synthesising large quantities of oestrogen, which is thought to play a key role in the development of the female reproductive system. A gene on the Y chromosome called TDF (*testis-determining factor*) appears to be responsible for testis formation and male development (Hodgkin, 1988).

Gonadal sex: This refers to the sexual or reproductive organs (ovaries in females and testes in males). *H-Y antigen,* controlled by genes on the Y chromosome, causes embryonic gonads to be transformed into testes. If H-Y antigen isn't present, gonadal tissue develops into ovaries (Amice *et al.*, 1989).

Hormonal sex: When the gonads are transformed into testes or ovaries, genetic influences cease and sex *hormones* take over biological sex determination. The male sex hormones are called *androgens,* the most important being *testosterone* (secreted by the testes). The ovaries secrete two distinct types of female hormone, *oestrogen* and *progesterone.* Although males usually produce more androgens, and females more oestrogens, both males and females produce androgens and oestrogens. So, strictly, there are no exclusively 'male' or 'female' hormones (Muldoon & Reilly, 1998).

Sex of the internal reproductive structures: The Wolffian ducts in males and the Müllerian ducts in females are the embryonic forerunners of the internal reproductive structures. In males, these are the prostate gland, sperm ducts, seminal vesicles, and testes. In females, they are the Fallopian tubes, womb, and ovaries.

Sex of the external genitals: In males, the external genitalia are the penis and scrotum. In females, they are the outer lips of the vagina (*labia majora*). In the absence of testosterone (which influences both the internal and external structures of chromosomal males), female structures develop (see text and Figure 36.1).

Hermaphroditism

The categories identified in Box 36.1 are usually highly correlated, so a person tends to be male (or female) in all respects. The categories also tend to be correlated with non-biological aspects of sex, including the sex the baby is assigned to at birth, how it's brought up, gender identity, gender-role identity, and so on. Either pre- or postnatally, however, disorders can occur leading to an inconsistency or low correlation between the categories. These disorders can tell us a great deal about the development of gender identity, gender role, and gender-role identity.

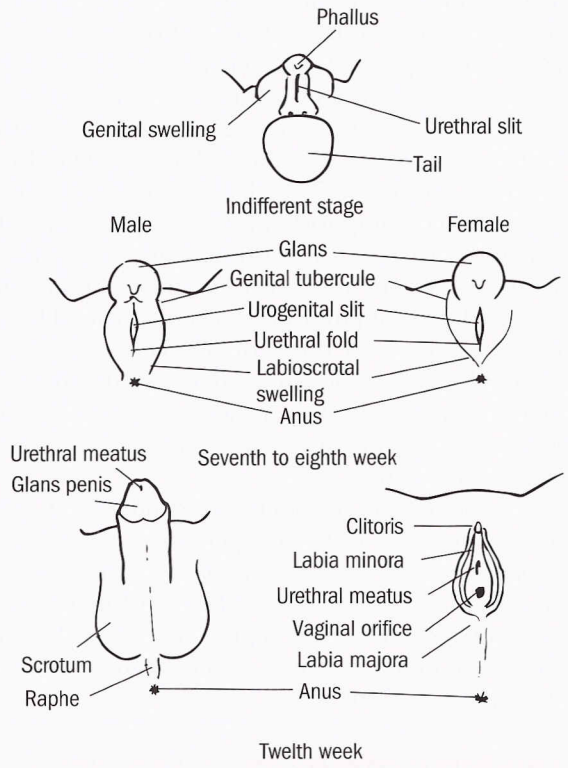

Figure 36.1 Prenatal differentiation of male and female genitalia. From a relatively undifferentiated state, development proceeds by means of the relative enlargement of structures that have analogues in members of the other sex (from Unger, R.K. (1979) *Female and Male,* New York: Harper & Row)

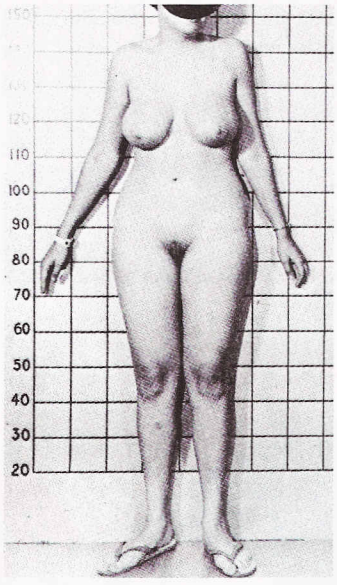
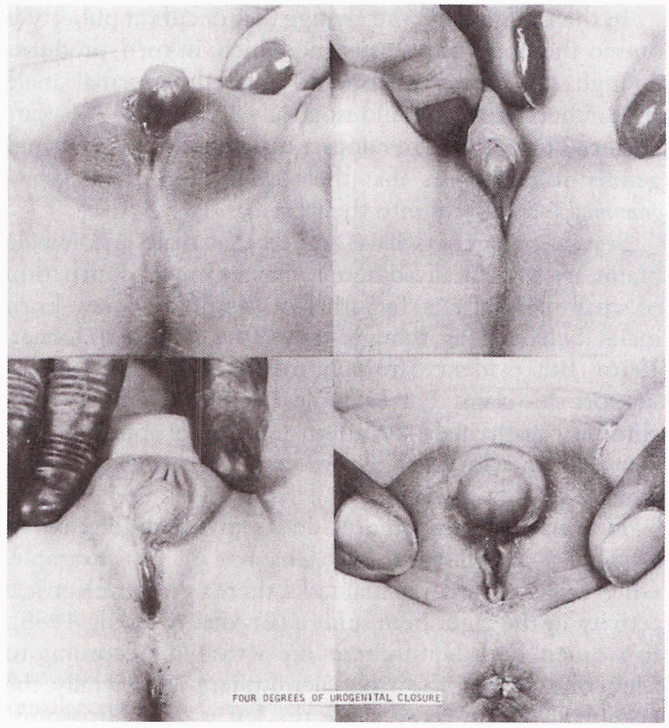


People with such disorders are called hermaphrodites. *True hermaphrodites* (from the mythical Greek god/goddess Hermaphrodite, who had attributes of both sexes) have either simultaneously or sequentially functioning organs of both sexes. They are very rare, and their external organs are often a mixture of male and female structures.

CASE STUDY 36.1 Mr Blackwell: hermaphrodite (Goldwyn, 1979)

- In an article called 'The fight to be male', Goldwyn cites the case of Mr Blackwell, only the 303rd true hermaphrodite in medical history.
- He's described as a handsome and rather shy 18-year-old Bantu. Although he had a small vaginal opening as well as a penis, he was taken to be a boy and brought up as such. But when he was 14 he developed breasts and was sent to hospital to discover why this had happened. It was found that he had an active ovary on one side of his body and an active testicle on the other. He expressed the wish to remain male, and so his female parts were removed.
- Goldwyn points out that if his internal ducts had been differently connected, Mr Blackwell could have actually fertilised himself without being able to control it.



Pseudohermaphrodites are more common. Although they too possess ambiguous internal and external reproductive structures, they're born with gonads that match their chromosomal sex (unlike true hermaphrodites).

- In *androgen insensitivity syndrome* (AIS) (or *testicular feminising syndrome*), pre-natal development in a chromosomally normal (XY) male is feminised. The internal reproductive structures of either sex fail to develop, and the external genitals fail to differentiate into a penis and scrotum. Normal-looking female external genitals and a shallow vagina are present at birth. At puberty, breast development occurs, but the individual fails to menstruate. Because of the presence of a very shallow (or 'blind') vagina, little or no surgery is needed for the adoption of a female appearance.

Adult with testicular feminisation (XY but with an insensitivity to androgen). These individuals are usually taller than the average female and tend to have an attractive 'female' physique (from Money & Ehrhardt, 1972, reprinted with permission)

- In *adrenogenital syndrome* (AGS), a chromosomally normal (XX) female is exposed to an excessive level of androgens during the critical period of prenatal sexual differentiation. While the internal reproductive structures are unaffected, the external structures resemble those of a male infant. For example, an enlarged clitoris appears to be a penis. These individuals are usually raised as females (see photographs opposite).
- In *DHT-deficient males* (or *5-alpha-reductase deficiency*), a genetic disorder prevents the normal prenatal conversion of testosterone into dihydrotestosterone (DHT). This hormone is necessary for the normal development of male external genitals. These males are usually incorrectly identified as females and raised as girls (but see Case Study 36.2).

Ambiguous appearance at birth of the genitalia of individuals with the adrenogenital syndrome (XX, but with excessive androgen during pre-natal differentiation) (from Money & Ehrhardt, 1972)

- In *chromosome abnormalities,* there's a discrepancy between chromosomal sex and external appearance, including the genitalia. The most common examples are Turner's syndrome (where a female individual has a single sex chromosome: XO) and Klinefelter's syndrome (where a male individual has an extra X chromosome: XXY).

Supporters of a biological approach argue that males and females are biologically programmed for certain kinds of activities compatible with male and female roles.

CASE STUDY 36.2 The Batista family: an overnight sex change? (Imperato-McGinley *et al.*, 1974)

- Imperato-McGinley *et al.* studied a remarkable family who live in Santo Domingo in the Dominican Republic (in the Caribbean). Of the ten children in the Batista family, four of the sons have changed from being born and growing up as girls into muscular men: they were born with normal female genitalia and body shape, but when they were 12, their vaginas healed over, two testicles descended, and they grew full-size penises.
- The Batistas are just one of 23 affected families in their village in which 37 children have undergone this change. All these families had a common ancestor, Attagracia Carrasco, who lived in the mid-eighteenth century. She passed on a mutant gene that shows only when carried by both parents.

In the Batista boys, the change that occurs at puberty is due to the flood of testosterone which, in turn, produces enough dihydrotestosterone to give the normal male appearance (which would normally happen 10–12 years earlier). Their ability to adopt a male gender identity and gender role suggests that their testosterone had *preprogrammed* masculinity into their brains.

Several researchers have argued that male and female brains are structurally different. For example, destruction of small parts of rats' hypothalami resulted in new-born males behaving as though they were female (Dorner, 1976). But evidence from human studies tends not to support this claim. For example, Daphne Went, although chromosomally male, has a female external appearance, is married, and leads an active and successful life as a woman (Goldwyn, 1979).

However, there's some evidence of sex differences in *hemispheric specialisation* (see Chapter 4). For example, when males perform spatial tasks, there's greater electrical activity in the right hemisphere (Bryden & Saxby, 1985). In women, both hemispheres are activated. According to McGlone (1980), the right hemisphere is generally the dominant one in men, while the left is generally dominant in women (see Boxes 36.1 and 36.2).

Despite evidence that the corpus callosum is larger overall in women and longer towards the back of the brain (an example of a *dimorphic* characteristic), Kimura (1993) has warned against accepting this evidence uncritically.

Box 36.2 The empathising-systemising (E-S) theory of female and male brains (Baron-Cohen, 2003a, 2003b)

- According to Baron-Cohen, the *female* brain is predominantly hardwired for *empathy*, while the *male* brain is predominantly hardwired for *understanding and building systems*. He calls this the *empathising-systemising* (E-S) *theory*.
- According to the theory, a person (whether male or female) has a particular 'brain type' There are three common brain types:
  - (i) for some individuals, empathising is stronger than systemising (the female brain/a brain of type E)
  - (ii) for others, systemising is stronger than empathising (the male brain/a brain of type S)
  - (iii) yet others are equally strong in their empathising and systemising ('balanced brain'/a brain of type B).
- Anecdotal evidence for the theory comes in the form of typical male and female choices of reading material (magazines) and hobbies.
- Scientific evidence shows that girls display more empathy and sensitivity towards others. For example, baby girls, as young as 12 months old, respond more empathically to others' distress, showing greater concern through more sad looks, sympathetic vocalisations and comforting. This echoes what's found in adulthood: more women report sharing their friends' emotional distress, and they also spend more time comforting people. Women are also more sensitive to facial expressions, better at decoding non-verbal communication, picking up subtle nuances from tone of voice or facial expression, or judging a person's character.
- Boys, from toddlerhood onwards, are more interested in cars, trucks, planes, guns and swords, building blocks, constructional toys and mechanical toys (i.e. *systems*). They seem to love putting things together, and 'building' things. Boys also enjoy playing with toys that have clear functions, buttons to press, things that will light up, or devices that will cause another object to move. Girls prefer dolls, soft toys and domestic articles (Golombok & Fivush, 1994).
- Males are also generally better at map-reading and mental rotation (both tests of systemising), and all these differences are reflected in 'typical' male and female *occupations*.
- Baron-Cohen believes that *hormonal factors* are the most likely cause of this difference between male and female brains.

(Based on Baron-Cohen, 2003a)

Boys 'systemising'

GENDER STEREOTYPES AND GENDER DIFFERENCES

ASK YOURSELF...

- What do you consider to be 'typical' feminine and masculine characteristics?
- Are these *merely* stereotypes, or do you think there are real, actual differences between males and females?
- If there are real differences, how do they arise?

There appears to be a high degree of agreement across 30 countries regarding the characteristics associated with each gender group (Williams & Best, 1994). For example, male-associated terms included 'aggressive', 'determined' and 'sharp-witted', while female-associated terms included 'cautious', 'emotional' and 'warm'. However, as far as actual differences are concerned, many stereotypes about males and females have little empirical support.

Box 36.3 Some findings relating to gender differences

Aggression: According to Maccoby & Jacklin (1974) and Weisfeld (1994), boys are more aggressive verbally and physically than girls, a difference which appears as soon as social play begins (around two-and-a-half years). While both sexes become less aggressive with age, boys and men remain more aggressive throughout development (see Chapter 29). However, some studies have shown that women score higher for certain kinds of indirect non-physical aggression (Durkin, 1995), while others have found no sex differences at all (e.g. Campbell & Muncer, 1994). According to Schaffer (2004), when both physical and non-physical aggression are taken into account, the gender difference almost disappears.

Verbal ability: From preschool to adolescence, the sexes are very similar with respect to verbal ability. But at age 11 females become superior, and this increases during adolescence and possibly beyond (Maccoby & Jacklin, 1974). But again, evidence suggests that any such differences are so small as to be negligible (Hyde & Linn, 1988).

Spatial ability: Males' ability to perceive figures or objects in space and their relationship to each other is consistently better than females' in adolescence and adulthood (Maccoby & Jacklin, 1974). But while there's male superiority on some spatial tasks, *within*-sex variability is large. Moreover, when between-sex differences are found, they're usually small (Durkin, 1995).

Mathematical ability: Mathematical skills increase faster in boys, beginning around age 12–13 (Maccoby & Jacklin, 1974). But while there are significant sex differences, these are in the *reverse* direction to the stereotype (Hyde *et al.*, 1990).

Maccoby & Jacklin's (1974) review concluded that hardly any of the many psychological attributes they examined clearly differentiated the sexes. This was subsequently confirmed by Ruble & Martin (1998). According to Schaffer (2004):

> ... personality and cognitive differences are far fewer in number than is commonly believed, and, where they do exist, moderate in extent and are quite probably becoming less evident as society redefines the role of the sexes.

The meaning of sex differences

Durkin (1995) suggests that:

> The overwhelming conclusion to be drawn from the literature on sex differences is that it is highly controversial.

A statistically significant difference *doesn't* imply a large behavioural difference. Rather, what determines a significant result is the *consistency* of the differences between groups. So, for example, if all the girls in a school scored 0.5 per cent higher than all the boys on the same test, a small but highly significant result would be produced (Edley & Wetherell, 1995).

Eagly (1983), however, has argued that in at least some cases a significant difference *does* reflect a substantial sex difference. By combining the results of different but comparable studies (*meta-analysis*), substantial sex differences emerge on some measures. According to Eagly, research has actually tended to conceal rather than reveal sex differences. However, the differences within each gender are at least as great as the differences between them (Maccoby, 1980).

CRITICAL DISCUSSION 36.1 The politics of sex difference research

- According to Edley & Wetherell (1995), debates in the nineteenth century about which sex is more intelligent were clearly more than just academic. Early attempts to prove that men's brains are larger and more powerful were just as much about justifying men's dominant social position as about trying to discover the 'natural' order of things.
- Similarly, the argument over inherent or natural sex differences is often part and parcel of a more general political debate about how society should be organised. For example, the claim that women are naturally more subjective, empathic, and emotional leads very neatly to the decision that they are best suited to child care and other domestic tasks which are devalued by men precisely because they're typically performed by women.
- More specifically, within psychology as a whole, but perhaps in the study of gender in particular, there's a strong bias towards publishing studies that have produced 'positive' results (where statistically significant sex differences have been found). When sex differences *aren't* found, the findings tend to remain unreported: the far more convincing evidence for 'sex similarity', therefore, is ignored, creating the very powerful impression that differences between men and women are real, widespread, and 'the rule'. Indeed, the very term 'sex similarities' sounds very odd (Jackson, 1992; Tavris, 1993; Unger, 1979). (See also Box 36.3.)

THEORIES OF GENDER DEVELOPMENT

Biosocial theory

According to Edley & Wetherell (1995), to ask 'What is the biological basis of masculinity (or femininity)?' is to pose a false question. In their view:

> It requires us to separate what cannot be separated: men [and women] are the product of a complex system of factors and forces which combine in a variety of ways to produce a whole range of different masculinities [and femininities].

Biosocial theory takes social factors into account in relation to biological ones. It sees the *interaction* between biological and social factors as important, rather than biology's direct influence. As far as other people are concerned, the baby's sex is just as important as its temperament. For example, the 'baby X' experiments (Smith & Lloyd, 1978) involved dressing babies in unisex snowsuits and giving them names that were sometimes in line with their true gender, and sometimes not. When adults played with them, they treated the babies according to the gender they *believed* them to be. This indicates that a person's (perceived) biological make-up becomes part of his/her social environment through others' reactions to them.

According to Money & Ehrhardt (1972), 'anatomy is destiny': how an infant is labelled sexually determines how it's raised or socialised. In turn, this determines the child's gender identity, and from this follow its gender role, gender-role identity, and sexual orientation. Psychologically, sexuality is *undifferentiated* at birth: it becomes differentiated as masculine or feminine in the course of the various experiences of growing up.

KEY STUDY 36.1 Pseudohermaphrodites and gender identity (Money & Ehrhardt, 1972)

- Money and Ehrhardt studied girls with AGS (see above, page 623), who were initially raised as boys. When the mistake was discovered, their genitals were surgically corrected, and they were reassigned and raised as girls.
- Money and Ehrhardt claim that it's possible to change the sex of rearing without any undue psychological harm being done, provided this occurs within a 'critical' or 'sensitive period' of about two-and-a-half to three years. But after this, reassignment to the opposite sex can cause extreme psychological disturbance.
- Money and Ehrhardt also studied ten people with testicular feminising syndrome. These people showed a strong preference for the female role, which also supports the view that sex of rearing is more important than biological sex. The case of Daphne Went (see text, above) also tends to support this view.

Evaluation of biosocial theory

◎ Just because some people appear to be flexible in their psychosexual identities doesn't in itself disprove that 'built-in biases' still have to be overcome (Diamond, 1978). Money and Ehrhardt's participants form an *atypical* sample, and there's no evidence that people *in general* are as flexible in their psychosexual orientation and identity.

CASE STUDY 36.3 The case of the penectomised twin (Money & Ehrhardt, 1972)

- As a result of an accident during circumcision, one of a pair of identical twins lost his penis (*penectomised*).
- At 22 months, 'he' was surgically castrated, oestrogen was given, and a vaginal canal constructed. He was subsequently raised as Joan.
- At age 4, Joan preferred dresses to trousers, took pride in her long hair, and was cleaner than her brother, Kevin. At age 9, although Joan had been the dominant twin since birth, she expressed this by being a 'fussy little mother' to Kevin.
- Money took these findings to support the view that gender identity (and gender role) is *learned*.

◎ The reversal of original sexual assignment is possible if it takes place early enough and is consistent in all respects, which includes the external genitalia conforming well enough to the new sex. But castration and the use of oestrogen clearly contributed to the ease of reassignment, and probably also account for Joan being shorter.

In *Man and Woman, Boy and Girl* (1972), Money and Erhardt referred to Joan's 'tomboyish traits' in passing, but focused on the ways she conformed to the stereotypes of female behaviour. No mention was made of the rejection and teasing she'd encountered in school. Significantly, when Joan had reached her teens she was an unhappy adolescent, with few friends, uncertain about her gender, and maintaining that boys 'had a better life'.

When Joan was 12, she (reluctantly) began taking oestrogen, and soon breast development and fat around the hips and waist began to appear. But she resisted any further (vaginal) surgery. By age 14, the female hormones were now in competition with her male hormonal system. She decided to stop living as a girl, changed her name back to John, and underwent sex change surgery just before his sixteenth birthday. A rudimentary penis was constructed, but this neither resembled nor performed like the real thing. His popularity with girls caused him terrible distress and unhappiness, and at 18 he tried to commit suicide on two separate occasions.

At 21, he had a second operation on his penis, which produced a significant improvement. Two years later, he met and fell in love with a single mother of three children – they married in 1990 (Colapinto, 2000). Colapinto met him in 1997 (he was then 31 years old and renamed David Reimer):

> The strongest impression I was left with was of John's intense, unequivocal masculinity. His gestures, walk, attitudes, vocabulary – none of them betrayed the least hint that he had been raised as a girl ... when conversation turns to his childhood ...

his voice ... takes on a tone of aggrievement and anger, and he tends to drop the pronoun 'I' from his speech, replacing it with the distancing 'you' – almost as if he were speaking about someone else altogether. Which, in a sense, he is.

He committed suicide in 2004.

ASK YOURSELF...

- What conclusions could you draw from the case of Joan/John?

◎ He'd collaborated on a book with a well-known New York journalist and appeared on the Oprah Winfrey show, declaring that Money had consigned him to a childhood of humiliation, confusion and misery (Usborne, 2004). These findings indicate that biology had ultimately proven irrepressible: gender identity is 'hardwired' into the brain virtually from conception (Diamond, 1982; Diamond & Sigmundson, 1997). As Diamond (in Usborne, 2004) says:

David didn't give permission for what was done to him. Even though he didn't have a penis, he still knew he was male.

Agreeing with Diamond, Reiner (in Fletcher, 1997) argues that:

The organ that appears to be critical to psychosexual development and adaptation is not the genitalia but the brain.

David Reimer in 2000

Sociobiological theory

Sociobiologists (evolutionary theorists: see Chapter 2) argue that gender has gradually evolved over the course of human development as part of our broader adaptation to the environment (Lumsden & Wilson, 1983). Males and females have developed different roles as a function of their respective contributions to reproduction and domestic labour (Wilson, 1978; Hoyenga & Hoyenga, 1979). The relatively greater physical strength, lung capacity, and so on of males make them better suited to hunting and defending territory and family. Females' child-bearing and milk-producing capacities make them ideally suited to child care and other nurturant roles.

According to *parental investment theory* (PIT) (Kenrick, 1994), females invest considerably more in reproduction than do males. Society came to be organised in sexually exclusive domestic partnerships as a way of meeting the female's needs for protection, and the male's need for preventing his mate from mating with other males. The consequence of this was the evolution of different courtship displays and roles (such as 'playing hard to get'), which are still evident in many (including western) cultures. According to Buss (1994), what females universally find attractive in males are the characteristics associated with the provision of resources. Men, by contrast, see physical beauty as being of greatest importance (see Chapter 28).

Evaluation of the sociobiological approach

CRITICAL DISCUSSION 36.2 Evolutionary psychology, sexual dimorphism and rape

- Like other *evolutionary psychologists*, Cosmides and Tooby (in Horgan, 1995) see the mind as comprising a number of specialised mechanisms or modules, designed by natural selection to solve problems that faced our hunter–gatherer ancestors, such as acquiring mates, raising children and dealing with rivals. The solutions often involve emotions such as lust, fear, affection, jealousy and anger.
- Evolutionary psychology is mainly concerned with *universal* features of the mind, but individual differences are seen as the expression of the same universal human nature as it encounters different environments. The crucial exception to this rule is *gender:* natural selection has constructed the mental modules of men and women very differently as a result of their divergent reproductive roles.
- Buss (1994) claims that there's a distinct gender gap in 'mate choice', and Thornhill & Wilmsen-Thornhill (1992) argue that human sexual psychology is *dimorphic* (the respective adaptations differ in men and women). The sexes differ in their feelings about whether, when and how often it's in their interests to mate.
- Because women are more selective about their mates and more interested in evaluating them and delaying intercourse, men, to get sexual access, must often break through female resistance. According to Thornhill and Wilmsen-Thornhill's *'rape adaptation hypothesis'*, during human evolutionary history there was enough directional

selection on males in favour of traits that solved the problem of forcing sex on a reluctant partner to produce a psychological tendency specifically towards rape.

- In other words, not only does this hypothesis recast an oppressive form of behaviour in a much more positive light (it's 'adaptive'), but it also represents it as a natural characteristic of men ('they can't help it'). Not surprisingly, it has been condemned as not simply trying to explain men's sexual coercion, but justifying it (Edley & Wetherell, 1995).

◎ The sociobiological approach has been criticised on several grounds. For example, dominance patterns are not, as sociobiological approaches assume, equated with greater aggression. In humans, at least, dominance often relates to status seeking, which implies the role of culturally determined values (Sayers, 1982). Sociobiological approaches to sex differences are also difficult to test: we have only incomplete knowledge about the ways in which our ancestors adapted to their environments. So, our hunches about which characteristics were adaptive and why differences between the sexes evolved are 'educated guesses' at best (see Chapter 2).

Freud's psychoanalytic theory

ASK YOURSELF...

- From what you know of Freud's theory of *psychosexual development,* try to outline his account of gender development (see Chapter 35).

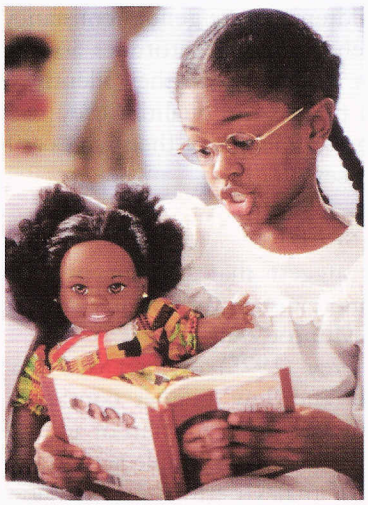
Freud's account of gender development is related to his explanation of moral development which, in turn, is part of his theory of psychosexual development. Up until the resolution of the Oedipus complex, gender identity is assumed to be flexible. Resolution of the Oedipus complex occurs through identification with the same-sex parent, and results in the acquisition of both a superego and gender identity. Like the development of conscience, Freud also saw the development of gender identity as being weaker in girls than boys.

Evaluation of the psychoanalytic approach

There are at least three reasons for doubting a Freudian interpretation of gender identity's development.

1. Children of a particular age don't appear to acquire gender identity in 'one fell swoop' (Krebs & Blackman, 1988).
2. Children who grow up in 'atypical' families (e.g. single-parent or lesbian couples) aren't necessarily adversely affected in terms of their gender identities (Golombok *et al.*, 1983). Indeed, children reared in fatherless families (whether lesbian or heterosexual) appear to have *more secure* attachments (Golombok *et al.*, 1997: see Chapter 32). When children raised in gay or lesbian households are followed up into adulthood, there are no indications that sexual identity or orientation is affected by having two same-sex parents. Studies of the parenting abilities of gays and lesbians indicate they're just as capable, warm and child-oriented as heterosexual parents – sometimes more so (presumably because of their greater motivation in the face of a sceptical and hostile world). The claim that children need a parent of each sex for healthy development isn't supported by the existing evidence (Golombok, 2000).
3. While identification might promote gender identity, children are aware of gender roles well before the age at which Freud believed their Oedipus complex is resolved. For example, boys prefer stereotypically masculine toys (such as trucks) and girls stereotypically feminine toys (such as dolls) in infancy (O'Brien *et al.*, 1983). (See Box 36.2.)

Social learning theory (SLT)



ASK YOURSELF...

- How do you think SLT tries to explain gender development? (See Chapter 35.)

According to *social learning theory* (SLT), one reason girls and boys learn to behave differently is that they're *treated differently* by their parents and others. As the 'baby X' study shows (see page 626), when informed of a child's biological sex, parents and others often react to it according to their gender-role expectations. Thus, girls and boys are often given different toys, have their rooms decorated differently, and are even spoken about in different terms (Rubin *et al.*, 1974).

A consistent and persistent finding is that fathers treat their children in a more gendered way than mothers (Maccoby, 1990). Typically, fathers interact in a more instrumental and achievement-oriented way, and give more attention to their sons, while mothers attend equally to sons and daughters (Quiery, 1998). However, Karraker *et al.* (1995) found that this strong *sex-typing* of infants at birth has declined, and that there were no differences between mothers and fathers in this respect.

SLT also emphasises the roles of *observational learning* and *reinforcement*. By observing others behaving in particular ways and then imitating that behaviour, children receive reinforcement from 'significant others' for behaviours considered to be *sex-appropriate* (Bandura, 1977b). Boys tend to be positively reinforced more for behaviours reflecting independence, self-reliance, and emotional control. But girls tend to be reinforced for dependence, nurturance, empathy and emotional expression (Block, 1979). Fathers tend to reinforce these sex-typed behaviours more than mothers do (Kerig *et al.*, 1993: see above).

Playing with dolls and displaying nurturant behaviour, and playing with guns and displaying assertive, even aggressive, behaviour, conform to female and male gender role expectations/stereotypes respectively. According to social learning theory, children receive parental reinforcement for displaying such gender-appropriate behaviours

Evaluation of SLT

Findings supporting SLT

- Sears *et al.* (1957) found that parents allowed sons to be more aggressive in their relationships with other children, and towards their parents, than daughters. For some mothers, 'being a boy' meant being aggressive, and boys were often encouraged to fight back. Although parents believe they respond in the same way to aggressive acts committed by boys and girls, they actually intervene much more frequently and quickly when girls behave aggressively (Huston, 1983).
- Boys were more likely to imitate aggressive male models than were girls (Bandura *et al.*, 1961, 1963). Children are also more likely to imitate a same-sex model than an opposite-sex model, even if the behaviour is 'sex-inappropriate' (see Chapter 35).
- Although parents are important models, SL theorists are also interested in media portrayals of males and females. A large body of evidence suggests that gender-role stereotypes are portrayed by the media, as well as by parents and teachers (Wober *et al.*, 1987). Moreover, children categorised as 'heavy' viewers of TV hold stronger stereotyped beliefs than 'lighter' viewers (Gunter, 1986).

Findings not supporting SLT

- According to Maccoby & Jacklin (1974), there are no consistent differences in the extent to which boys and girls are reinforced for aggressiveness or autonomy. In fact, there appears to be remarkable uniformity in how the sexes are socialised. This is supported by Lytton & Romney (1991), who found very few sex differences in terms of parental warmth, overall amount of interaction, encouragement of achievement or dependency, restrictiveness and discipline, or clarity of communication.
- Although Bandura *et al.*'s research is often cited, the evidence concerning imitation and modelling is actually inconclusive, and some studies have failed to find that children are more likely to imitate same-sex models than opposite-sex models. Indeed, children have been shown to prefer imitating behaviour that's 'appropriate' to their own sex *regardless* of the model's (Maccoby & Jacklin, 1974).
- The view that TV can impact upon a passively receptive child audience with messages about sex-role stereotyping, and mould young children's conceptions of gender is oversimplistic. For Gunter & McAleer (1997), children respond selectively to particular characters and events, and their perceptions, memories, and understanding of what they've seen may often be mediated by the dispositions they bring with them to the viewing situation. While 'heavy' TV viewers might hold stronger stereotyped beliefs than other children, no precise measures were taken of the programmes they actually watched.
- While modelling plays an important role in children's socialisation, there's no consistent preference for the same-sex parent's behaviour (Hetherington, 1967). Instead, children prefer to model the behaviour of those with whom they have most contact (usually the mother). Also, there's no significant correlation between the extent to which parents engage in sex-typed behaviours and the strength of sex-typing in their children (Smith & Daglish, 1977). However, fathers' adoption of either traditional (sex-typed) or egalitarian attitudes has been found to correlate with four-year-olds' perceptions of sex roles (Quiery, 1998).

Cognitive–developmental theory (CDT)

The cognitive–developmental approach (Kohlberg, 1969; Kohlberg & Ullian, 1974) emphasises the child's participation in developing both an understanding of gender and gender-appropriate behaviour (see Chapter 35).

Children's discovery that they're male or female *causes* them to identify with members of their own sex (*not* the other way round, as psychoanalytic and SL theories suggest). While rewards and punishments influence children's choices of toys and activities, these don't mechanically strengthen stimulus–response connections, but provide children with information about when they're behaving in ways that other people deem appropriate (Bandura, 1977a).

According to CD theorists, young children acquire an understanding of the concepts *male* and *female* in three stages.

Box 36.4 Stages in the development of gender identity

Stage 1 (Gender labelling or basic gender identity): This occurs somewhere around age three (Ruble, 1984) and refers to the child's recognition that it's male or female. According to Kohlberg, knowing one's gender is an achievement that allows us to understand and categorise the world. But this knowledge is fragile, and children don't yet realise that boys invariably become men and girls always become women.

Stage 2 (Gender stability): By age 4–5, most children recognise that people retain their genders for a lifetime. But children still rely on superficial signs (such as the length of a person's hair) to determine their gender (Marcus & Overton, 1978).

Stage 3 (Gender constancy or consistency): At around age 6–7, children realise that gender is *immutable*. So, even if a woman has her hair cut very short, her gender remains constant. Gender constancy represents a kind of *conservation* (see Chapter 34) and, significantly, appears shortly after the child has mastered the conservation of quantity (Marcus & Overton, 1978).

Children of 4–5 might be confused about this person's gender

Once children acquire gender constancy, they come to value the behaviours and attitudes associated with their sex. Only at this point do they identify with the adult figures who possess the qualities they see as being most central to their concepts of themselves as male or female (Perry & Bussey, 1979).

Evaluation of CDT

- Evidence suggests that the concepts of gender identity, stability and constancy occur in that order across many cultures (Munroe *et al.*, 1984).
- Slaby & Frey (1975) divided two- to five-year-olds into 'high' and 'low' gender constancy. The children were then shown a silent film of adults simultaneously performing a series of simple activities. The screen was 'split', with males performing activities on one side and females on the other. Children rated as 'high' in gender constancy showed a marked same-sex bias, as measured by the amount of visual attention they gave to each side of the screen. This supports Kohlberg's belief that gender constancy is a *cause* of the imitation of same-sex models, rather than an effect.
- Children actively construct their gender-role knowledge through purposeful monitoring of the social environment. They engage in *self-socialisation,* rather than passively receiving information (Whyte, 1998).

ASK YOURSELF...

- According to CDT, what is the relationship between gender constancy and the child's gender-appropriate behaviour?

- A major problem for CDT is that it predicts there should be little or no gender-appropriate behaviour before gender constancy is achieved. But even in infancy, both sexes show a marked preference for stereotypical male and female toys (Huston, 1983: see Box 36.2). While such children might have developed a sense of gender identity, they are, as far as CDT is concerned, some years away from achieving gender stability and constancy (Fagot, 1985).

Gender-schematic processing theory (GSPT)

Gender-schematic processing theory (GSPT) addresses the possibility that gender identity *alone* can provide children with sufficient motivation to assume sex-typed behaviour patterns (e.g. Bem, 1985; Martin, 1991). Like SLT, this approach suggests that children learn 'appropriate' patterns of behaviour by observation. However, consistent with CDT, children's active cognitive processing of information also contributes to their sex-typing.

Children learn that strength is linked to the male sex-role stereotype and weakness to the female stereotype, and that some dimensions (including strength–weakness)

are more relevant to one gender (males) than the other (Rathus, 1990). So, a boy learns that the strength he displays in wrestling (say) affects others' perceptions of him. Unless competing in some sporting activity, most girls don't see this dimension as being important. But while boys are expected to compete in sports, girls aren't, and so a girl is likely to find that her gentleness and neatness are more important in the eyes of others than her strength (Rathus, 1990).

According to GSPT, then, children learn to judge themselves according to the traits considered to be relevant to their genders. Consequently, the self-concept becomes mixed with the *gender schemas* of a particular culture which provides standards for comparison. The theory sees gender identity as being sufficient to produce 'sex-appropriate' behaviour. The labels 'boy' and 'girl', once understood, give children the basis for mixing their self-concepts with their society's gender schemas. Children with gender identity will actively seek information about gender schemas, and their self-esteem will soon become influenced by how they 'measure up' to their gender schema (Rathus, 1990: see Chapter 33).

Jane Couch (the 'Fleetwood Assassin'), women's world welterweight boxing champion, after winning her sex discrimination case in 1998 against the British Boxing Board of Control over its refusal to grant her a licence to box professionally

Cultural relativism

This really represents the most direct challenge to the biological approach. If gender differences reflect biological differences, then we'd expect to find the same differences occurring in different cultures. Any differences that exist between cultures with regard to gender roles (*cultural relativism*) support the view that gender role is *culturally determined*.

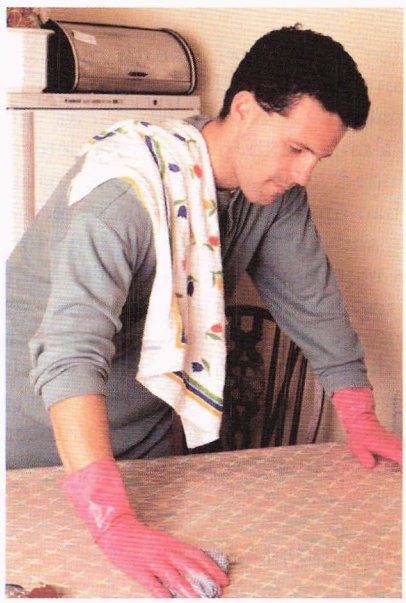
Margaret Mead (1935) claimed that the traits we call masculine and feminine are completely unrelated to biological sex. Just as the clothing, manner and headdress considered to be appropriate in a particular society, at a particular time, aren't determined by sex, so temperament and gender role aren't biologically but culturally determined. She studied three New Guinea tribes living quite separately from each other within about a 100-mile radius.

- The *Arapesh* were gentle, loving and cooperative. Boys and girls were reared in order to develop these qualities, which in western society are stereotypically feminine. Both parents were said to 'bear a child', and men took to bed while the child was born.
- The *Mundugumor* were ex-cannibals. Both males and females were self-assertive, arrogant, fierce, and continually quarrelling, and they both detested the whole business of pregnancy and child-rearing. Sleeping babies were hung in rough-textured baskets in a dark place against the wall and when they cried, someone would scratch gratingly on the outside of the basket.
- The *Tchambuli* represented the reversal of traditional western gender roles. Girls were encouraged to take an interest in the tribe's economic affairs, and the women took care of trading and food gathering. Men were considered sentimental, emotional, and incapable of making serious decisions, spending much of the day sitting around in groups, gossiping and 'preening' themselves.

However, by 1949, after she'd studied four other cultures (Samoa, Manus, Iatmul and Bali), Mead had rather dramatically changed her views about gender roles. From a rather extreme 'cultural determinism', she now concluded that women were 'naturally' more nurturing than men, expressing their creativity through childbearing and childbirth, and are superior in intellectual abilities requiring intuition. While motherhood is a 'biological inclination', fatherhood is a 'social invention': by implication, societies which encourage a gender role division other than that in which dominant, sexually energetic men live with passive, nurturant women are 'going against nature'. Significantly, by this time she'd given birth to a child of her own (Booth, 1975)!

Are there cultural universals?

A finding which may seem to support Mead in her search for 'natural' differences is that there's no known society in which the female does the fighting in warfare (including the Tchambuli and Arapesh: Fortune, 1939). However, there's more to aggression than warfare. Malinowski (1929), studying the Trobriand Islanders, reported that, in order to foster their tribe's reputation for virility, groups of women would catch a man from another tribe, arouse him to erection and rape him! This 'gang rape' was carried out in a brutal manner, and the women often boasted about their achievement.



ASK YOURSELF...

- Even if men are, universally, the hunters and war-makers, does this necessarily mean that males are naturally more aggressive than females?

According to Wade & Tavris (1994), early researchers assumed that men are naturally aggressive (and women are naturally nurturant). Consequently, they often defined nurturing in a way that excluded the altruistic, caring activities of men. For example, men can nurture the family by providing food for mother and child, and sometimes by going off to fight in faraway places, sacrificing their lives if necessary, in order to provide a safe haven for their people.

While most cultures distinguish between 'men's' and 'women's' work and while biological factors undoubtedly play some part in the sexual division of labour (see Box 36.2), the content of this work varies enormously between cultures. As Hargreaves (1986) observes, in some cultures:

> ... men weave and women make pots, whereas in others these roles are reversed; in some parts of the world women are the major agricultural producers, and in others they are prohibited from agricultural activity.

What's men's and women's work is a matter of convention

Box 36.4 Are there more than two genders?

- Among the Sakalavas in Madagascar, boys who are thought to be pretty are raised as girls and readily adopt the female gender role. Similarly, the Alentian Islanders in Alaska raise handsome boys as girls; their beards are plucked at puberty and they are later married to rich men. They too seem to adapt quite readily to their assigned gender role.
- Studies of certain Native American peoples reveal the possibility of more than two basic gender roles. For example, the '*berdache*', a biological male of the Crow tribe, simply chooses not to follow the ideal role of warrior. Instead, he might become the 'wife' of a warrior, but he's never scorned or ridiculed by his fellow Crows. (Little Horse in the film *Little Big Man*, starring Dustin Hoffman, was a 'berdache'.)
- The Mohave Indians recognised four distinct gender roles: (i) traditional male; (ii) traditional female; (iii) 'alyha'; and (iv) 'hwame'. The 'alyha' was a male who chose to live as a woman (to the extent of mimicking menstruation by cutting his upper thigh and undergoing a ritualistic pregnancy), and the 'hwame' was a female who chose to become a man.

Western culture has no formally recognised and accepted equivalent of the berdache. However, in recent times, as the economic lives of men and women have become more similar (see Chapter 38), we have at least informally developed some acceptance of berdache-like alternatives. For example, the concept of *androgyny* (Bem, 1974) refers to people who've developed both the 'masculine' and 'feminine' sides of themselves more fully than most. Similarly, the concept of *sexual orientation* implies an awareness that relationships aren't simply an expression of a single inborn norm (Price & Crapo, 1999).

CONCLUSIONS

While every known culture distinguishes between male and female, the evidence for the truth of sex stereotypes is inconclusive. Although anatomical sex is universal and unchangeable, *gender,* which refers to all the duties, rights and behaviours a culture considers appropriate for males and females, is a *social invention*. It's gender that gives us a sense of personal identity as male or female (Wade & Tavris, 1994).

An even stronger argument for the *social construction* of gender comes from studies of societies in which gender reversal is relatively commonplace or, more importantly, where there are more than two genders. All the perspectives discussed in this chapter have contributed to our understanding of that process, and they should be seen as complementary explanations (Whyte, 1998).

CHAPTER SUMMARY

- Feminist psychologists distinguish between **sex/sexual identity** and **gender/gender identity**.
- There's little empirical support for actual gender differences in terms of either aggression or verbal, spatial, or mathematical abilities.

- Biologically, sex refers to **chromosomal sex**, **gonadal sex**, **hormonal sex**, sex of the **internal reproductive structures** and sex of the **external genitalia**. While these are usually highly correlated with each other, in **hermaphroditism/pseudohermaphroditism**, pre- and postnatal disorders produce an inconsistency between these categories.
- Major types of pseudohermaphroditism include **androgen insensitivity syndrome** (AIS)/**testicular feminising syndrome**, **adrenogenital syndrome** (AGS), and **dihydrotestosterone** (DHT)**-deficiency/5-alpha-reductase deficiency**.
- According to the **biological approach**, males and females are biologically programmed for certain activities compatible with gender roles.
- While studies of **hemispheric specialisation** are consistent with some of the claimed male–female differences in cognitive abilities, evidence that the corpus callosum is sexually dimorphic is inconclusive.
- The **empathising-systemising** (E-S) **theory** maintains that female brains are hardwired for empathy and sensitivity towards others, while male brains are hardwired for constructing systems. These differences are reflected in male/female differences from birth, and in adult skills and occupations.
- **Biosocial theory** stresses the **interaction** of social and biological factors. A person's (perceived) biological make-up (such as sex) becomes part of his or her social environment through others' reactions to it.
- Money and Ehrhardt claim that there's a **critical** or **sensitive** period for the development of gender identity. But the case of a **penectomised** boy raised as a girl tend to support the claim that gender identity and role are **biologically determined**.
- According to **sociobiologists**, gender has evolved as part of human beings' broader adaptation to the environment. **Parental investment theory** (PIT) claims that sexually exclusive domestic partnerships meet the female's need for protection and the male's need for preventing his mate from mating with other males.
- **Psychoanalytic theory** sees gender identity as being related to moral and overall psychosexual development. But gender identity develops much more gradually than Freud claimed, and studies of children who grow up in 'atypical' families show that their gender identity isn't adversely affected.
- According to **social learning theory** (SLT), girls and boys learn to behave differently through being **treated differently** by parents and others. SLT also stresses the role of **observational learning** and **reinforcement** for imitating sex-appropriate behaviours.
- Evidence is inconclusive regarding the importance for imitation of the **sex-appropriateness** of a model's behaviour and the model's sex. There's no consistent preference for the same-sex parent's behaviour, but rather for the parent the child spends most time with.
- According to the **cognitive–developmental approach**, children's discovery that they're male or female **causes** them to identify with and imitate same-sex models. Three **stages** in the development of gender identity are **gender labelling/basic gender identity**, **gender stability**, and **gender constancy/consistency**.
- **Gender-schematic processing theory** (GSPT) maintains that gender identity **alone** can provide a child with sufficient motivation to assume sex-typed behaviour. Children learn to judge themselves according to the traits seen as relevant to their genders, resulting in self-concepts that are mixed with the **gender schemas** of a particular culture.
- According to **cultural relativism**, any differences in gender roles between cultures are likely to be **culturally determined**.
- The enormous cultural diversity of the content of men's and women's work, and the existence of more than two genders in some Native American peoples, strongly suggests that gender is **socially constructed**.

Links with other topics/chapters

- Feminist psychology and sociobiology fall at the two extremes of the continuum of the *nature–nurture* (heredity–environment) *debate* (Chapter 50).
- Regarding the *corpus callosum,* it hasn't been clearly established that the number of fibres is the crucial male–female difference (as has been assumed). Also, sex differences in cognitive functioning have yet to be related to the size of the corpus callosum (Kimura, 1993) (Chapter 4).
- The question of male/female differences in aggression/violence is relevant to understanding common reactions to *female murderers* and perpetrators of other *violent crimes* (Chapter 46).
- According to Denmark *et al.* (1988), ignoring studies that fail to produce non-significant sex differences represents a form of *sexism* or *gender bias* in psychological research (Chapter 47). In turn, these constitute *ethical issues,* because of their potential consequences for females (Chapter 48).
- Females' more empathic brains are relevant to understanding gender differences in relation to *prosocial behaviour* (Chapter 30).
- Baron-Cohen (2003a, 2003b) has found that, at birth, girls look longer at a face, and boys look longer at a suspended mechanical mobile (Chapter 16).
- According to Baron-Cohen (2003a, 2003b), people with *autism* may have an extreme male brain (Chapter 40).
- The observation that adults prefer to spend time with babies who respond to them in 'rewarding' ways, and 'demanding' babies tend to receive more attention than 'passive' babies, is consistent with biosocial theory and also illustrates the concept of a *reactive gene-environment correlation* (Chapter 50).

- TV and other media are investigated in relation to both *aggression* (Chapter 29) and *prosocial behaviour* (Chapter 30), as well as sex-role stereotyping.
- Cultural relativism, and the related cultural determinism, represent one extreme end of the *nature–nurture* continuum (Chapter 50).

ADOLESCENCE

INTRODUCTION AND OVERVIEW

The word 'adolescence' comes from the Latin *adolescere* meaning 'to grow into maturity'. As well as being a time of enormous physiological change, adolescence is also marked by changes in behaviour, expectations, and relationships with both parents and peers. In western, industrialised societies, there's generally no single initiation rite signalling the passage into adulthood. This makes the transition more difficult than it appears to be in more traditional, non-industrialised societies. Relationships with adults in general, and parents in particular, must be renegotiated in a way that allows the adolescent to achieve greater independence. This process is aided by changing relationships with peers.

1950s films such as *Rebel Without A Cause*, starring James Dean (left), have been seen as helping to create the concept of the 'rebellious teenager'

Historically, adolescence has been seen as a period of transition between childhood and adulthood. But writers today are more likely to describe it as one of *multiple transitions,* involving education, training, employment and unemployment, as well as transitions from one set of living circumstances to another (Coleman & Roker, 1998).

This change in perspective in many ways reflects changes in the adolescent experience compared with those of previous generations: it starts five years earlier, marriage takes place six to seven years later than it did, and cohabitation, perhaps as a prelude to marriage, is rapidly increasing (Coleman & Hendry, 1990). Passage into adulthood may also be deferred by the delay in acquiring an income: not only has there been an extension in compulsory education, but pressure on the workforce to become more highly skilled places a premium on continuing education (Hendry, 1999).

Coupled with these 'adulthood-postponing' changes, in recent years adolescents have enjoyed greater self-determination at steadily younger ages. Yet this greater freedom carries with it more risks and greater costs when errors of judgement are made. As Hendry (1999) says:

... 'dropping out' of school, being out of work, teenage pregnancy, sexually transmitted diseases, being homeless, drug addiction and suicide, are powerful examples of the price that some young people pay for their extended freedom ...

NORMATIVE AND NON-NORMATIVE SHIFTS

ASK YOURSELF...

- What kinds of transitions do adolescents in western societies experience?
- Are these necessarily the same for all adolescents?

One way of categorising the various transitions involved in adolescence is in terms of *normative* and *non-normative shifts* (Hendry & Kloep, 1999; Kloep & Hendry, 1999).

- *Normative, maturational shifts* include the growth spurt (both sexes), menarche (first menstruation), first nocturnal emissions ('wet dreams'), voice breaking (boys), changes in sexual organs, beginning of sexual arousal, changed romantic relationships, gender-role identity, changed relationships with adults, increasing autonomy and responsibility.
- *Normative, society-dependent shifts* include the change from primary to secondary school, leaving school, getting started in an occupation, acquiring legal rights for voting, sex, purchasing alcohol, driving licence, military service, and cohabitation.
- *Non-normative shifts* include parental divorce, family bereavement, illness, natural disasters, war, incest, emigration, disruption of peer network, risk-taking behaviours, 'disadvantage' (because of gender, class, regional or ethnic discrimination), physical and/or mental handicap.

According to Kloep & Hendry (1999):

Although all adolescents have to cope with the psychosocial challenges associated with their maturing body, new relationships with parents and peers, with school and the transitions toward employment, a growing number encounter additional problems like family disruption, economic deprivation or social or cultural changes ...

A normative shift may become non-normative, if, say, there are other circumstances that cause a normal developmental 'task' to become more difficult. An example would be the unusually early or late onset of puberty.

PUBERTY: THE SOCIAL AND PSYCHOLOGICAL MEANING OF BIOLOGICAL CHANGES

Puberty and body image

Adjusting to puberty is one of the most important adjustments that adolescents have to make (Coleman & Hendry, 1990). Even as a purely biological phenomenon, puberty is far from being a simple, straightforward process. While all adolescents experience the same bodily changes (see Box 37.1 and Figure 37.1, page 637), the sequence of changes may vary within individuals (*intraindividual asynchronies:* Alsaker, 1996). For example, for some girls menstruation may occur very early on in puberty, while for others it may occur after most other changes (e.g. growth spurt, breast development) have taken place.

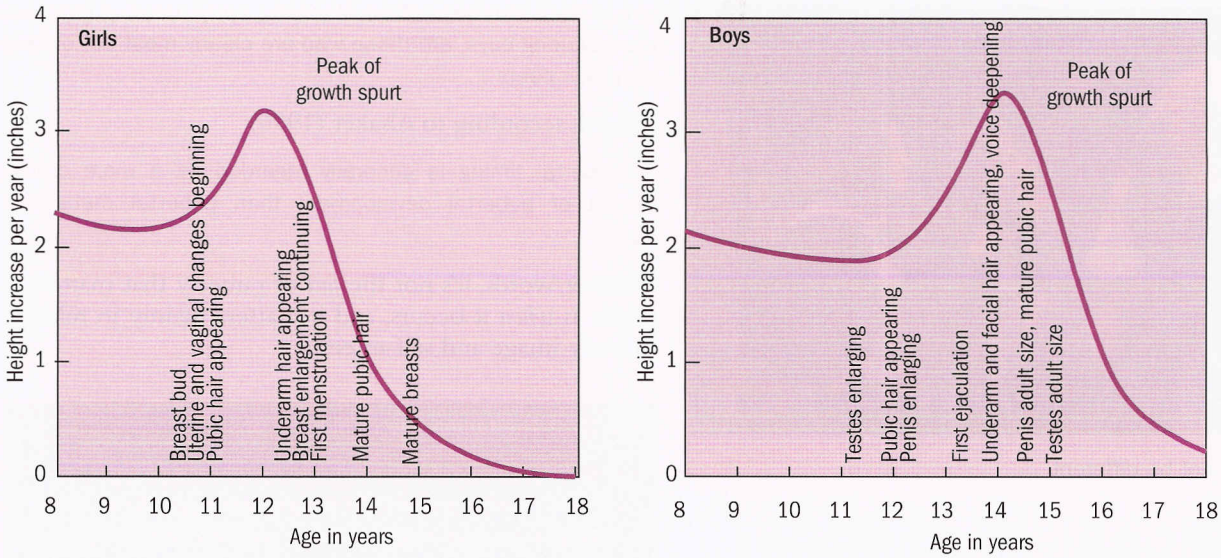

Figure 37.1 The development of secondary sex characteristics. The curved lines represent the average increase in height from eight to 18 years of age. The characteristics shown may occur earlier or later in a person's development, but usually occur in the order shown (based on Tanner, 1978, and Tanner & Whitehouse, 1976). Reproduced with the permission of the copyright holders, Castlemead Publications.

Major changes in puberty

Physiologically, puberty begins when the seminal vesicles and prostate gland enlarge in the male, and the ovaries enlarge in the female. Both males and females experience the *adolescent growth spurt*. Male *secondary sex characteristics* include growth of pubic and then chest and facial hair, and sperm production. In females, breast size increases, pubic hair grows and menstruation begins.

Box 37.1 Adolescents' brains

- According to some neuroscientists, the brain undergoes some fundamental restructuring during adolescence, just as it does during the earliest years of childhood. While the *plasticity* of the infant's and young child's brain is widely accepted (see Chapter 4), this has traditionally been seen as stopping at puberty.
- However, two MRI studies, one *longitudinal* (which followed up the same set of youngsters over several years: Giedd *et al.*, 1999), the other *cross-sectional* (which compared a group of 14-year-olds with a group in their mid-twenties: Sowell *et al.*, 1999) suggest otherwise.
- Areas of the cortex that deal with more basic functions, such as sensory and motor processing, do indeed stabilise in early childhood. But the parietal and frontal lobes, which are specialised for visuospatial and 'executive functions' (e.g. planning and self-control) respectively, show a *growth surge* between the ages of 10 and 12.
- This sudden 'bulking up' is then followed by an equally dramatic *reduction* in size, which continues right through the teenage years and into the early twenties. The grey-matter density decreases, indicating that the number of synaptic connections have become fewer (consistent with the theory that a mature brain involves the 'pruning' of connections in order to strengthen those that remain).It stops only when these areas have reached their adult proportions.
- This late shrinkage is taken to be a sign of maturation. As McCrone (2000) puts it:

  ... brains are believed to develop mainly by a pruning of their neural thickets to form orderly processing paths.

- According to Rapoport (in Connor, 2004):

  One could speculate that some of the more immature aspects of adolescent behaviour may be due to the lack of maturity of some parts of the frontal lobes of the brain.

(Based on McCrone, 2000)

According to Davies & Furnham (1986), the average adolescent isn't only sensitive to, but also critical of, his or her changing physical self. Because of gender and sexual development, young people are inevitably confronted, perhaps for the first time, by cultural standards of beauty in evaluating their own body images (via the media and the reactions of others).This may produce a *non-normative shift* in the form of dieting practices, leading to eating disorders (see Chapter 44). Young people may be especially vulnerable to teasing and exclusion if they're perceived by their peers as over- or under-weight (Kloep & Hendry, 1999).

The need to not be different

Gender differences

ASK YOURSELF...

- Do you consider puberty to be a more difficult transition for boys or girls *in general?*
- Why?

While puberty may be a normative, maturational shift, it may be a more difficult transition for girls than boys. This is because of the *subjective meaning* of bodily change (what it means for the individual), which mirrors the *sociocultural significance* of puberty (its significance for society). According to the *cultural ideal hypothesis* (CIH) (Simmons & Blyth, 1987), puberty will bring boys *closer* to their physical ideal (an increase in muscle distribution and lung capacity produces greater stamina, strength and athletic capacities), while girls move *further away* from theirs.

For girls, who begin puberty on average two years ahead of boys, it's normal to experience an increase in body fat and rapid weight gain, thus making their bodies less like the western cultural ideal of the thin, sylph-like supermodel. In addition, they have to deal with menstruation, which is negatively associated with blood and physical discomfort (Crawford & Unger, 1995).

The importance of timing

If the CIH is valid, it follows that *early maturing boys* will be at an *advantage* relative to their 'on-time' and late-maturing peers (they'll be moving faster towards the male ideal). By the same token, *early maturing girls* will be at a *disadvantage* (they'll be moving faster away from the female ideal). As Bergevin *et al.* (2003) put it:

> ... girls who enter puberty early relative to other girls are typically far ahead of virtually all boys. Likewise, boys who enter puberty late are far behind most boys and behind almost all girls. These two sets of adolescents, early-maturing girls and late-maturing boys, are those who are clearly most out of step with their peers ...

Indeed, according to Alsaker (1996):

> ... pubertal timing is generally regarded as a more crucial aspect of pubertal development than pubertal maturation itself.

In other words, it's not the *fact* of puberty that matters as much as *when* it occurs, and it matters mainly in relation to body image and self-esteem.

Box 37.2 The falling age of puberty onset

- One in six girls reaches puberty by the age of eight, compared with one in 100 a generation ago. Also, 1 in 14 eight-year-old boys has pubic hair (an early indicator of puberty), compared with 1 in 150 of their fathers' generation.
- Bristol University's Institute of Child Health tracked the development of 1150 children from birth. It's the first study of puberty in Britain since the 1960s (see Figure 37.1). Not only are children starting puberty earlier, but it's lasting longer. The reasons are unclear, but likely causes are higher oestrogen levels in mothers, diet, lifestyle, and pollution. There could also be a genetic link, since the mothers of girls who begin puberty earlier also matured earlier.
- Separate research has found that the average age of menarche has fallen below 13 in Britain for the first time. It's now 12 years, 10 months, compared with 13 years, 6 months in 1969.
- These findings mean that children could be developing sexually before they have the emotional maturity to deal with the possible consequences.

(Based on Peek, 2000)

ASK YOURSELF...

- A common finding is that early-maturing girls and late-maturing boys suffer lower self-esteem. Why do you think this might be?

Box 37.3 Why do early-maturing girls and late-maturing boys feel less good about themselves?

- One popular explanation is the *deviancy hypothesis* (DH), according to which those who are 'off-time' in physical maturation are socially deviant compared with peers of the same age and gender (Wichstrom, 1998). Since girls begin puberty on average two years before boys, early-maturing girls are the first to enter this deviant position, followed by late-maturing boys.

- An alternative explanation is the *developmental readiness hypothesis* (DRH) (Simmons & Blyth, 1987). In the case of early or sudden puberty, too little time will have been spent on ego development during latency, with early maturing girls once more being most affected. (This explanation is similar to Coleman's *focal theory:* see page 646.)
- As far as the CIH is concerned, the suggestion that the pubertal girl moves further away from the western stereotyped female ideal may *not* be true. *Both* boys and girls move closer to their ideals, provided they don't put on excessive weight (Wichstrom, 1998).

According to Wichstrom, the CIH is sensitive to changes in time and context. For example, in Norway there may be less emphasis on stereotypical male stature compared with the USA and UK. Perhaps also the embarrassment and negative affect experienced by American girls when starting their periods and becoming sexually responsive is less prevalent among Norwegian girls, due to relatively greater openness about adolescent sexuality (Wichstrom, 1998).

THEORIES OF ADOLESCENCE

Hall's theory: adolescence as storm and stress

This is probably the earliest formal theory of adolescence. Influenced by Darwin's evolutionary theory, Hall (1904) argued that each person's psychological development *recapitulates* (repeats/recaptures) both the biological and cultural evolution of the human species. He saw adolescence as a time of 'storm and stress' (or *Sturm und Drang*), which mirrors the volatile history of the human race over the last 2000 years.

Some evidence suggests that emotional reactions are more *intense* and *volatile* during adolescence compared with other periods of life: see Key Study 37.1). However, more important indicators of storm and stress are (a) mental disorder, and (b) delinquent behaviour.

KEY STUDY 37.1 Volatile adolescents (Csikszentmihalyi & Larson, 1984)

- Seventy-five Chicago-area high-school students from diverse social and racial backgrounds were asked to wear electronic pagers for a week. Every two hours, the pager signalled to the students that they were to write a description of what they were doing and how they felt about it.
- After a week, they filled out questionnaires about both their general moods and their specific mood during particular activities.
- About 40 per cent of waking time was spent pursuing leisure activities, the other 60 per cent being more or less equally divided between 'maintenance activities' (such as commuting and eating) and 'productive activities' (such as studying and working).
- Particularly revealing were the adolescents' extreme mood swings, from extreme happiness to deep sadness (and vice versa) in less than an hour. Adults usually require several hours to reach the same emotional peaks and troughs.

Studies of mental disorder

Several studies have found that *early maturing girls* score higher on measures of depressive feelings and sadness (e.g. Alsaker, 1992; Stattin & Magnusson, 1990), although this was true only when the measures were taken before or simultaneously with changing schools (Petersen *et al.*, 1991). They've also been reported to have more psychosomatic (psychophysiological) symptoms (e.g. Stattin & Magnusson, 1990), to display greater concerns about eating (e.g. Brooks-Gunn *et al.*, 1989), and to score higher on Offer's psychopathology scale (e.g. Brooks-Gunn & Warren, 1985).

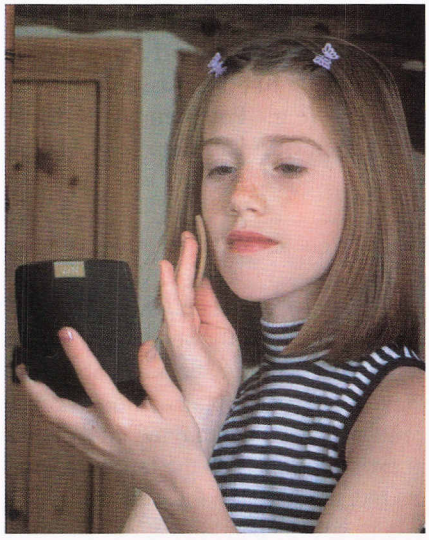
As far as *early maturing boys* are concerned, the evidence is much more mixed (Alsaker, 1996). While early maturation is usually found to be advantageous, it's also been found to be associated with more psychopathology (e.g. Petersen & Crockett, 1985), depressive tendencies, and anxiety (e.g. Alsaker, 1992).

KEY STUDY 37.2 The 'Isle of Wight' study (Rutter *et al.*, 1976)

- This involved a large, representative sample of 14–15-year-olds (more than 2000), whose parents and teachers completed a behaviour questionnaire about them.
- More detailed data were obtained from two subsamples: (i) 200 randomly selected from the total population; (ii) 304 with extreme scores on the teacher/parent questionnaires (suggesting 'deviant' behaviour).
- Those in both subsamples were given questionnaires and tests, and interviewed by psychiatrists. The major findings regarding rates of psychiatric disorder among the adolescents, compared with a sample of ten-year-olds and the adolescents' parents, are shown in Table 37.1.

Table 37.1 Percentage of ten-year-olds, 14–15-year-olds, and the latter's parents, displaying psychiatric disorder

	Ten-year-olds	14–15-year-olds	Adults (parents)
Males	12.7	13.2	7.6
Females	10.9	12.5	11.9



According to Rutter *et al.* (1976):

- there's a rather modest peak in psychiatric disorders in adolescence

- although severe clinical depression is rare, some degree of inner turmoil may characterise a sizeable minority of adolescents. While it's not a myth, neither should it be exaggerated
- a substantial proportion of those adolescents with psychiatric problems had had them since childhood; also, when problems did first appear during adolescence, they were mainly associated with stressful situations (such as parents' marital discord):

... adolescent turmoil is fact, not fiction, but its psychiatric importance has probably been overestimated in the past ... (Rutter *et al.*, 1976)

In western societies, while some adolescents may display affective disturbances or disorders, it's a relatively small minority who'll show clinical depression or report 'inner turmoil' (Compas *et al.*, 1995). Instead, the majority worry about everyday issues, such as school and examination performance, finding work, family and social relationships, self-image, conflicts with authority, and the future generally (Gallagher *et al.*, 1992).

Pre-teens are growing up faster than ever before, and early-maturing girls are most at risk of mental disorder and delinquency

Studies of delinquent behaviour

Caspi *et al.* (1993) studied all the children born in Dunedin, New Zealand between April 1972 and March 1973, following them up every two years from ages 3 to 15. Compared with on-time (menarche 12.5–13.5 years) and late maturers (after 13.5), early maturing girls were more at risk for:

- *early delinquency* (breaking windows, getting drunk, making prank phone calls, stealing from other pupils at school)
- *familiarity with delinquent peers* (having friends or knowing others who engaged in these activities), and
- *delinquency* (shoplifting, car theft, smoking marijuana, using weapons).

However, the risk for early delinquency was greater only in mixed-sex schools, and (as with a sample of Swedish girls studied by Magnusson *et al.*, 1985) early maturers were likely to mix with older peers. As for boys, off-time (early and late) maturation has been shown to be related to alcohol consumption, with late maturers also being at risk for later alcohol problems (Anderson & Magnusson, 1990).

Erikson's theory: identity crisis

Erikson (1963) believed that it's human nature to pass through a genetically determined sequence of *psychosocial stages,* spanning the whole lifespan. Each stage involves a struggle between two conflicting personality outcomes, one of which is positive (or *adaptive*), while the other is negative (or *maladaptive*). Healthy development involves the adaptive outweighing the maladaptive.

The major challenge of adolescence is to establish a strong sense of *personal identity.* The dramatic onset of puberty (combined with more sophisticated intellectual abilities: see Chapter 34) makes adolescents particularly concerned with finding their own personal place in adult society.

In western societies adolescence is a *moratorium,* an authorised delay of adulthood, which frees adolescents from most responsibilities and helps them make the difficult transition from childhood to adulthood.

The Jewish bar mitzvah marks the 13-year-old boy's entry into manhood. But to the rest of society, he's still just a teenager

Although this is meant to make the transition easier, it can also have the opposite effect. Most of the societies studied by cultural anthropologists have important public ceremonies to mark the transition from childhood to adulthood. This is in stark contrast to western, industrialised nations, which leave children to their own devices in finding their identity. Without a clearly defined procedure to follow, this process can be difficult – for both adolescents and their parents (see *Generation gap* below).

Does society create identity crisis?

ASK YOURSELF...
- Can you think of any inconsistencies or contradictions that adolescents face between different aspects of their development?
- How do they perceive their social status?

As well as the perceived absence of 'rites of passage' in western society, a problem for both adolescents and their parents is the related lack of consensus as to where adolescence begins and ends, and precisely what adolescent rights, privileges and responsibilities are. For example, the question 'When do I become an adult?' elicits a different response from a teacher, doctor, parent and police officer (Coleman, 1995).

The 'maturity gap' refers to the incongruity of achieving biological maturity at adolescence without simultaneously being awarded adult status (Curry, 1998). According to Hendry & Kloep (1999):

> ... young people, as they grow up, find themselves in the trap of having to respond more and more to society's demands in a 'responsible' adult way while being treated as immature and not capable of holding sound opinions on a wide range of social matters.

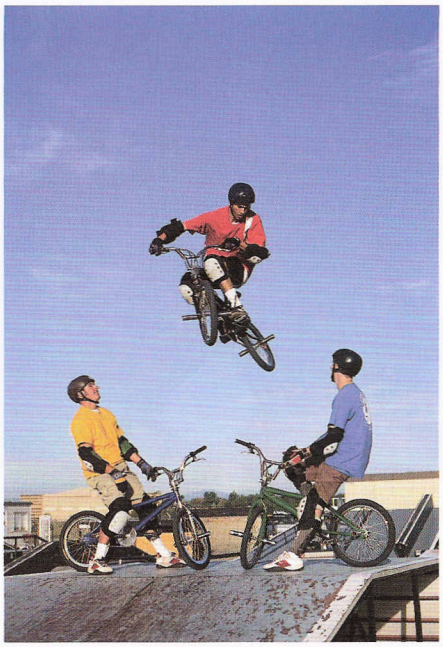
One possible escape route from this trap is *risk-taking behaviour* (see below and Critical Discussion 37.1, page 642). As well as having to deal with the question 'Who am I?', the adolescent must also ask 'Who will I be?'. Erikson saw the creation of an adult personality as achieved mainly through choosing and developing a commitment to an occupation or role in life. The development of *ego identity* (a firm sense of who one is and what one stands for) is positive, and can carry people through difficult times.

When working with psychiatrically disturbed soldiers in the Second World War, Erikson coined the term *identity crisis* to describe the loss of personal identity which the stress of combat seemed to have caused. Some years later, he extended the use of the term to include:

> severely conflicted young people whose sense of confusion is due ... to a war within themselves.

Boy soldiers in Butembo, Zaire, fighting against the regime of President Mobutu Sese Seko

Role confusion



Failure to integrate perceptions of the self into a coherent whole results in *role confusion,* which, according to Erikson, can affect several areas of life, as described below.

- *Intimacy:* a fear of commitment to, or involvement in, close relationships, arises from a fear of losing one's own identity. This may result in stereotyped and formalised relationships, or isolation.
- *Time perspective:* the adolescent is unable to plan for the future or retain any sense of time. It's associated with anxieties about change and becoming an adult.
- *Industry:* difficulty in channelling resources in a realistic way into work or study, both of which require commitment. As a defence, the adolescent may find it impossible to concentrate, or become frenetically engaged in a single activity to the exclusion of all others.
- *Negative identity:* engaging in abnormal or delinquent behaviour (such as drug-taking, or even suicide) as an attempt to resolve the identity crisis. This extreme position, which sets such adolescents apart from the crowd, is preferable to the loneliness and isolation that come with failing to achieve a distinct and more functional role in life ('a negative identity is better than no identity').

Related to Erikson's claims about negative identity is *risk-taking behaviour.* Hendry (1999) asks if risk-taking is:

> ... part of the psychological make-up of youth – a thrill-seeking stage in a developmental transition – a necessary rite of passage en route to the acquisition of adult skills and self-esteem ...

Many teenagers seek out excitement, thrills and risks as earnestly as in childhood, perhaps to escape a drab existence, or to exert some control over their own lives and to achieve *something.*

Thrill seeking: a rite of passage into adulthood?

CRITICAL DISCUSSION 37.1 Sex and drugs

- Traditionally, what parents of teenagers have most feared is that their children will engage in (particularly unprotected) sex and (especially hard) drugs. Recent research suggests that they can feel a little less fearful about both.
- Figures for 1998 showed that the rate of teenage pregnancies was at its highest for almost a decade (47 per 1000 girls under 18 – 101,500 – compared with 45.6 per 1000 in 1991), with Britain having the highest rate in Europe. Pregnant teenagers are also increasingly likely to opt for abortion.
- However, teenage pregnancies in England *fell* between 1998 and 2001 by 9 per cent. Although they rose again slightly in 2002, they were still lower among 14–16-year-olds than in 1992. This recent fall probably reflects more teenagers actually using protection. Pill use soared by more than a third among 16–17-year-olds between 1998 and 2002.
- A recent survey of 2600 15–16-year-old boys and girls shows that use of illegal drugs among British youngsters has dropped for the first time since the 1960s. An exception is girls in Northern Ireland. Figures for 1999 show a 'startling' turnaround since 1995, when UK teenagers had the highest rates of drug use in the world. Certain drugs, such as ecstasy, have acquired a bad name and have gone out of fashion. Nevertheless, drug use is widespread, and heroin use has actually *increased* (although it remains a minority choice).

(Based on Boseley, 2000; Hinsliff & Revill, 2004; Norton, 2000b; Vasagar, 2000)

For some, delinquency may be the solution: it could actually be *adaptive* as a way of facilitating self-definition and expressing autonomy (Compas *et al.*, 1995).

According to Bergevin *et al.* (2003):

> ... One of the challenges of the self in adolescence is with identifying the ways that one is unique and how one is similar to others. Maintaining a sense of individuality while trying to fit into the group is an important task for adolescents. Emphasising differences can lead to loneliness and alienation, while emphasising similarities may impede the development of autonomy.

Such conflict seem to be largely absent in societies where the complete transition to adulthood is officially approved and celebrated at a specific age, often through a particular ceremony. These enable both the individual and society to adjust to change and enjoy a sense of continuity (Price & Crapo, 1999).

CROSS-CULTURAL STUDY 37.1

Initiation into adulthood in non-western cultures

- Cohen (1964) looked at 45 non-industrialised societies which held adulthood ceremonies. In societies where adult skills were hard and dangerous, or where father–son relationships were weak but men had to cooperate in hard work, male initiation rituals were dramatic and painful. They allowed the boy to prove his manhood to the community – and to himself.
- Sometimes they're designed to give boys strength, often by associating them with animals or plants. For example, in the Merina of Madagascar, the boy is associated with the banana tree, which bears much fruit resembling the erect penis (an ideal symbol of virility and fertility). The to-be-initiated boy is removed from his mother's home (a symbol of his attachment to her), before being circumcised in the company of men.
- Brown (1963) described 'rites of passage' for girls in 43 societies from all major regions of the world. They most commonly occur where young girls continue to live and work in their mothers' home after marriage, but they also sometimes occur even when young women permanently leave home, and here they involve genital operations or extensive tattooing. These dramatically help the girl understand that she must make the transition from dependent child to a woman, who'll have to fend for herself in a male-dominated environment (Price & Crapo, 1999).
- In recent years, *infibulation* (the most extreme form of female circumcision) has become a global human rights issue. Its purpose is to preserve the virginity of young girls before marriage, and to tame the disturbing power of women. In many traditional Islamic countries, especially Sudan, Ethiopia and Somalia, millions of young girls continue to undergo painful and risky genital operations.

Although the act of infibulation may, from a western perspective, deindividualise and depersonalise women:

... it acts as a transition or a rite of passage to a greater female adult collective; one where women hold relatively few advantages in a male-dominated world. It may in fact be one of the few positive status markers for women in traditional Islamic societies ... (Price & Crapo, 1999)

Xhosa boys in Bisho, South Africa, singing traditional manhood songs as part of a six-week-long ceremony, which begins with circumcision

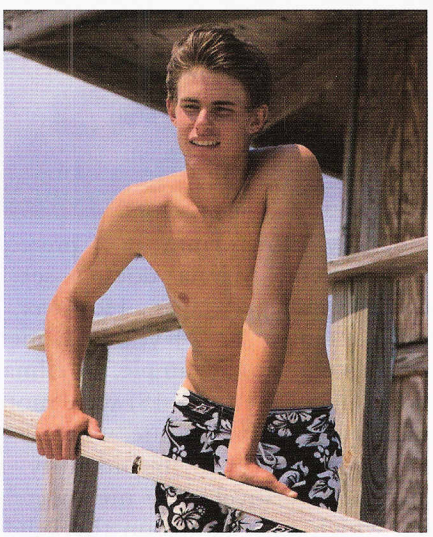
ASK YOURSELF...

- Do you agree with Price and Crapo's comments about female circumcision?
- Is our condemnation of such practices simply a reflection of western values, or are there universal principles and standards that apply regardless of who's being judged and who's doing the judging?

Segall *et al.* (1999) maintain that tension and some antisocial behaviour are only to be expected in western societies, due to the much longer adolescent and youth period:

... without a clear marking by ritual, no or little productive role or community participation, no child-rearing duties, and distance from observing adult activities.

According to Coleman & Roker (1998), an important trend in adolescence research is an increasing focus on identity development among ethnically diverse populations, such as young black women (e.g. Robinson, 1997) and mixed-race young people (Tizard & Phoenix, 1993). Coleman and Roker believe that notions of identity and identity formation are likely to become more central to the study of adolescence as this life stage becomes longer and more fragmented, and entry into adulthood becomes more problematic.



Studies of self-esteem

Tests of Erikson's theory have typically used measures of self-concept (especially *self-esteem*) as indicators of crisis. Girls' dissatisfaction with their appearance begins during puberty, along with a decline in self-esteem (Crawford & Unger, 1995). Comparisons between *early- and late-maturing girls* indicate that dissatisfaction with looks is associated with the rapid and normal weight gain that's part of growing up (Attie & Brooks-Gunn, 1989; Blyth *et al.*, 1981).

Early maturers have a less positive body image, despite the fact that they date more and earlier. Also, sexual activity is more problematic for adolescent girls (as it is for females in general): there are persisting double standards regarding sex (as reflected in the terms 'slag' and 'stud' for sexually active females and males respectively), together with differential responsibility for contraception and pregnancy (see Critical Discussion 37.1).

However, Offer *et al.* (1988) deny there's any increase in disturbance of the self-image during early adolescence. Although such disturbance is more likely in early than late adolescence, only a very small proportion of the total adolescent population is likely to have a negative self-image or very low self-esteem (Coleman & Hendry 1990).

By contrast, *early maturing boys* feel more attractive (Tobin-Richards *et al.*, 1983) and tend to be more satisfied with their bodies, looks, and muscle development (Blyth *et al.*, 1981; Simmons & Blyth, 1987). However, Alsaker (1996) refers to two studies, which have found a correlation between pubertal boys' dissatisfaction with their bodies and the development of pubic and body hair. She asks if this reflects some contemporary images of men in advertisements, and a new trend for men to shave their bodies and be *less* hairy.

American tennis player Andy Roddick relaxing in Miami

Most of these (and other similar) studies have been conducted in the USA, UK, and other English-speaking countries. But a study of a very large, nationally representative Norwegian sample found that the global self-esteem of both late-maturing boys and girls suffered, while early and on-time maturers (of both sexes) enjoy equally high self-esteem (Wichstrom, 1998).

Marcia's theory: identity statuses

In an extension of Erikson's work, Marcia (1980) proposed four *statuses* of adolescent identity formation, which characterise the search for identity. A mature identity can be achieved only if an individual experiences several crises in exploring and choosing between life's alternatives, finally arriving at a *commitment* or *investment of the self* in those choices.

Box 37.4 The four identity statuses proposed by Marcia (1980)

Table 37.2 Four identity statuses as defined by high/low commitment and high/low crisis

		Degree of crisis	
		High	**Low**
Degree of commitment to particular role/values	**High**	Identity achievement	Foreclosure
	Low	Moratorium	Diffusion (or confusion)

Diffusion/confusion: The individual hasn't really started thinking about the issues seriously, let alone formulated any goals or made any commitment. (This represents the *least mature* status.)

Foreclosure: The individual has avoided the uncertainties and anxieties of crisis by quickly and prematurely committing to safe and conventional (parental) goals and beliefs. Alternatives haven't been seriously considered.

Moratorium: This is the height of the crisis as described by Erikson. Decisions about identity are postponed while the individual tries out alternative identities, without committing to any particular one.

Identity achievement: The individual has experienced a crisis but has emerged successfully with firm commitments, goals and ideology. (This represents the *most mature* status.)

Although identity moratorium is a prerequisite for identity achievement, Marcia doesn't see the four statuses as Erikson-type stages. However, evidence suggests that, amongst 12–24-year-old men, they're broadly age-related. For example, Meilman (1979) reported that younger men (12–18) were more likely to experience diffusion or foreclosure, whereas older men were increasingly likely to be identity achievers. Irrespective of age, relatively few men were achieving moratorium, which casts doubt on the validity of the theory.

Several *longitudinal* studies have indicated clear patterns of movement from foreclosure and diffusion to moratorium and achievement (Kroger, 1996). However, when applied to females, even Marcia (1980) accepts that his statuses work 'only more or less'.

Sociological approaches: generation gap

Sociologists see *role change* as an integral aspect of adolescent development (Coleman, 1995). Changing school or college, leaving home, and beginning a job, all involve new sets of relationships, producing different and often greater expectations. These expectations themselves demand a substantial reassessment of the self-concept and speed up the socialisation process. Some adolescents find this problematic because of the wide variety of competing socialising agencies (such as the family, mass media and peer group), which often present *conflicting* values and demands (see discussion above of the identity crisis).

Sociologists also see socialisation as being more dependent on the adolescent's *own generation* than on the family or other social institutions (*auto-socialisation:* Marsland, 1987). As Marsland says:

> The crucial meaning of youth is withdrawal from adult control and influence compared with childhood ...

Young people withdraw into their peer groups, and this withdrawal is (within limits) accepted by adults. What Marsland is describing here is the *generation gap.*

ASK YOURSELF...

- While adolescents and their parents are, by definition, different generations, does this necessarily and inevitably mean that there's a generation gap – that is, that there'll be conflict between them because they occupy 'different worlds'?

Parent–adolescent relationships

According to Hendry (1999):

> Adolescence as a transition from childhood to adulthood requires changes from child–parent relationships to young-adult–parent relationships ...

Failure to negotiate new relationships with parents, or having highly critical or rejecting parents, is likely to make adolescents adopt a negative identity (Curry, 1998). Also, parents who rated their own adolescence as stormy and stressful reported more conflict in their relationships with adolescent children and were less satisfied with their family (Scheer & Unger, 1995). Parents of adolescents in general are often going through a time of transition themselves, reappraising their life goals, career and family ambitions, and assessing whether they've fulfilled their expectations as parents.

However, for most adolescents relationships with parents become more equal and reciprocal, and parental

authority comes to be seen as open to discussion and negotiation (e.g. Coleman & Hendry, 1990; Hendry *et al.*, 1993). The study by Hendry *et al.* (1993) also suggests that relationships with mothers and fathers don't necessarily change in the same ways and to the same extent.

KEY STUDY 37.3 Adolescent–parent relationships (Hendry *et al.*, 1993)

- In a longitudinal Scottish study, Hendry *et al.* found that parents were chosen in preference to friends when discussing progress and problems at school, and careers, but not necessarily more personal matters.
- Mothers were preferred over fathers as confidantes in all areas except careers and sex (boys) and problems with mothers (both sexes). Most girls and nearly half the boys chose to confide in their mothers over problems with friends, and nearly half the girls and a third of the boys conveyed doubts about their own abilities to her.
- These figures suggest a *disengagement* by fathers. Girls tend to be very uncomfortable discussing pubertal issues with their fathers, and learn almost nothing from them about puberty. The mother's role in enforcing family rules brings her into conflict with the children more readily, but she's still seen as being supportive and caring, not 'distanced' like the father.

Studies conducted in several countries have found that young people get along well with their parents (e.g. Hendry *et al.*, 1993; Kloep & Tarifa, 1993), adopt their views and values, and perceive family members as the most important 'significant others' in their lives (McGlone *et al.*, 1996). Furthermore, most adolescents who had conflicts with their parents already had poor relationships with them before puberty (Stattin & Klackenberg, 1992).

Generational harmony – not generation gap

Disagreements between young people and their parents are similar everywhere in Europe: Greece (Besevegis & Giannitas, 1996), Italy (Jackson *et al.*, 1996), Scotland (Hendry *et al.*, 1993), Germany (Fischer *et al.*, 1985), Albania and Sweden (Kloep & Tarifa, 1993). Teenagers have daily quarrels about how long or often they may stay out, how much they should help at home, tidiness of their bedrooms, volume of music, and school achievement.

According to Jackson *et al.* (1996) disagreements can arise because:

- parents expect greater independence of action from their teenagers
- parents don't wish to grant as much autonomy as the adolescent demands (with young women having more conflict than young men over independence)
- parents and adolescents have different personal tastes and preferences.

Despite this potential for conflict, evidence suggests that competence as an independent adult can best be achieved within the context of a secure family environment, where exploration of alternative ideas, identities and behaviour is allowed and actively encouraged (Barber & Buehler, 1996). So, while detachment and separation from the family are necessary and desirable, young people don't have to reject their parents in order to become adults in their own right (Ryan & Lynch, 1989; Hill, 1993: see Chapter 32).

Peer relationships

Adolescent *friendship groups* (established around mutual interests) are normally embedded within the wider network of *peer groups* (which set 'norms', provide comparisons and pressures to conform to 'expected' behaviours). Friendship groups reaffirm self-image, and enable the young person to experience a new form of intimacy and learn social skills (such as discussing and solving conflicts, sharing and self-assertion). They also offer the opportunity to expand knowledge, develop a new identity, and experiment away from the watchful eyes of adults and family (Coleman & Hendry, 1990).

Generally, peers become more important as providers of advice, support, feedback and companionship, as models for behaviour and as sources of comparison with respect to personal qualities and skills. But while peer groups and friendship groups become important points of reference in social development and provide social contexts for shaping day-to-day values, they often *support* traditional parental attitudes and beliefs. Hence, peer and friendship groups can work in concert with, rather than in opposition to, adult goals and achievements (Hendry, 1999).

Coleman's focal theory: managing one change at a time

According to Coleman & Hendry (1990), most theories of adolescence help us to understand young people with serious problems and those belonging to minority or deviant groups. However, what's needed is a theory of *normality*. The picture that emerges from the research as a whole is that while adolescence is a difficult time for some, for the majority it appears to be a period of relative stability. Coleman's (1980) *focal theory* is an attempt to explain how this is achieved.

The theory is based on a study of 800 6-, 11-, 13-, 15- and 17-year-old boys and girls. Attitudes towards self-image, being alone, heterosexual and parental relationships, friendships and large-group situations, all changed as a function of age. More importantly, concerns about different issues reached a peak at different ages for both sexes.

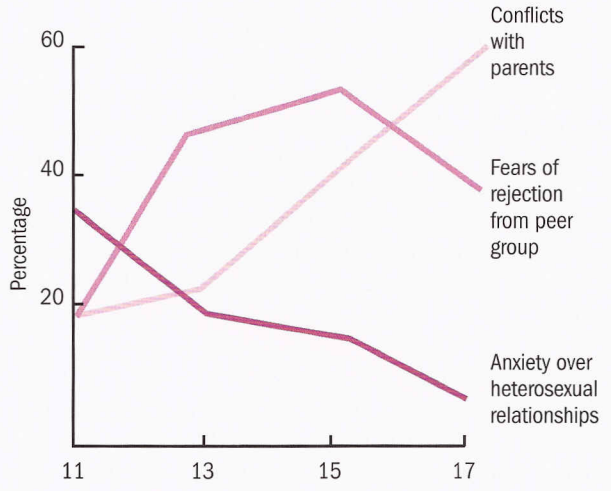


Figure 37.2 Peak ages of the expression of different themes. These data are for boys only (from Coleman & Hendry, 1990)

Particular sorts of relationship pattern come into *focus* (are most prominent) at different ages, although no pattern is specific to one age. The patterns overlap and there are wide individual differences.

Coleman believes that adolescents are able to cope with the potentially stressful changes as well as they do by dealing with one issue at a time. They spread the process of adaptation over a span of years, attempting to resolve one issue first before addressing the next. Because different problems and relationships come into focus and are dealt with at different points during the adolescent years, the stresses resulting from the need to adapt don't all have to be dealt with together.

According to Coleman & Hendry (1990), it's those adolescents who, for whatever reason, must deal with *more than one issue* (or normative shift) at a time, who are most likely to experience difficulties. If normative shifts coincide with non-normative ones, the situation is even more problematic (Hendry & Kloep, 1999).

Coleman's original findings have been successfully replicated by Kroger (1985) with large North American and New Zealand samples. Others have successfully tested hypotheses derived from the theory. For example, Simmons & Blyth (1987) predicted that, if change (such as puberty)

- occurred at too young an age (causing the individual to be developmentally 'off-time')
- was marked by sharp discontinuity (i.e. sudden change) or
- involved accumulation of significant and temporally close issues (important shifts occurred together)

then adjustment would be more difficult. Their results strongly supported their predictions.

CONCLUSIONS

Adolescence involves a number of important transitions from childhood to adulthood, including puberty. The potential for storm and stress in western societies is increased by the lack of clear definitions regarding when adulthood is reached. This makes the task of attaining an adult identity, as well as relationships with parents, more difficult compared with non-industrialised societies.

However, adolescence in western societies isn't as problem-ridden as the popular stereotype would have it. If any serious problems do arise, they're directly linked to *rapid social change* (Dasen, 1999), with the associated extension of adolescence and youth. Young people aren't given a productive role to play when entering adult society (Segall *et al.*, 1999).

While most of the major theories of adolescence paint a picture of adolescence as an *inherently* difficult developmental stage, the evidence suggests that this isn't necessarily so. Certain groups may be more vulnerable than others (such as early maturing girls), but the majority seem to cope well. According to Coleman's theory, it *isn't* adolescence itself that's stressful, but the timing and combination of the transitions faced by young people.

CHAPTER SUMMARY

- Adolescence involves **multiple transitions**. Compared with previous generations, it begins sooner and ends later. Various 'adulthood-postponing' changes have coincided with increased freedom at earlier ages.
- These transitions or **shifts** can be categorised as **normative maturational**, **normative society-dependent** and **non-normative**. Normative shifts can become non-normative, as when puberty begins unusually early or late.

- **Puberty** involves the **adolescent growth spurt** and the development of **secondary sex characteristics** (both sexes). While girls typically enter puberty two years before boys, there are important individual differences within each sex (such as **intraindividual asynchronies**).
- Adolescents evaluate their changing body images in terms of cultural standards of beauty, especially as these relate to weight. According to the **cultural ideal hypothesis** (CIH), girls move further away from their physical ideal and **early maturing girls** will face a double disadvantage. **Early maturing boys** will move fastest towards their physical ideal.
- Hall's **recapitulation theory** saw adolescence as a time of **storm and stress**. While mood swings are more common during adolescence, rates of **mental disorder** (and **delinquency rates**) are higher only in early maturing girls and adolescents with problems prior to puberty. The evidence for **off-time** maturation in boys is more mixed.
- According to Erikson, adolescence involves a conflict between **ego identity** and **role confusion**. In western societies, adolescence is a **moratorium**, intended to help ease the transition to adulthood. However, the lack of clear definitions of adulthood may contribute to the adolescent **identity crisis**.
- Role confusion can take the form of **negative identity**, related to which is **risk-taking behaviour**. These problems are largely absent in societies which mark the transition to adulthood by **initiation ceremonies**.
- While **self-esteem** may decline in early adolescence, especially in girls, this affects only a very small proportion of all adolescents. But research findings from English-speaking countries may not generalise to other cultures.
- Marcia's four **identity statuses** are defined by high/low **commitment** and **crisis**. Although these aren't meant to be Erikson-type stages, the evidence suggests otherwise, but only for men.
- **Sociological approaches** stress **role change**, the **conflicting** values and demands of different socialising agencies, and **auto-socialisation**, which produces the **generation gap**.
- Renegotiating relationships with parents is necessary, and while there are inevitable disagreements, adult status is probably best achieved within the context of a **secure family environment**.
- **Friendship groups** (as 'sub-groups' of the wider **peer group**) assume much greater significance during adolescence, such as helping to shape basic values. But these values are often **consistent** with parents' values, goals and achievements.
- According to Coleman's **focal theory**, most adolescents cope as well as they do by spreading the process of adaptation over several years, dealing with one issue at a time. Having to deal with more than **one issue at a time** is stressful, especially if changes occur too early or suddenly.

Links with other topics/chapters

- The importance of puberty for changes in the adolescent's body image is mirrored by the fact that the *bodily self* is probably the first aspect of the *self-concept* to develop in the baby (Chapter 33).
- Research conducted in Scotland in 1996/1997 found that young people who have sex before the age of 15 often regret it. Young people need more help to feel in control of their sexual activities, such as being helped to develop relationship and negotiation skills (Chapter 12).
- Erikson's psychosocial theory is *psychodynamic,* but differs from Freud's *psychoanalytic theory* in fundamental ways (Chapter 2 and 42).
- One of the major differences between Erikson and Freud concerns the crucial times for development. For Freud, the first five years are critical, while Erikson adopts a *life-span developmental approach* (Chapters 38 and 39).
- Teenage use of *hard, recreational* (class A) drugs is part of the wider problem of *substance use and dependence* (Chapter 8).
- Marcia's admission that his theory only loosely applies to females (but much better to males) illustrates *androcentrism* – that is, taking the male experience as the standard and applying it to both men and women. Erikson's theory has been criticised for similar reasons (Gilligan, 1982: Chapters 38 and 47).
- Adolescence coincides with parents experiencing their own transition, sometimes referred to as the *mid-life crisis* (Chapter 38).

ADULTHOOD

INTRODUCTION AND OVERVIEW

Assuming that we enjoy a normal lifespan, the longest phase of the life cycle will be spent in adulthood. Until recently, however, personality changes in adulthood attracted little psychological research interest. Indeed, as Levinson *et al.* (1978) have observed, adulthood is:

> ... one of the best-kept secrets in our society and probably in human history generally.

This chapter attempts to reveal some of these secrets by examining what theory and research have told us about personality change in adulthood, including the occurrence of crises and transitions.

Many theorists believe that adult concerns and involvements are patterned in such a way that we can speak about *stages* of adult development. However, evidence concerning the predictability of changes in adult life (or what Levinson, 1986, calls *psychobiosocial transitions*) is conflicting. Three kinds of influence can affect the way we develop in adulthood (Hetherington & Baltes, 1988):

1. *normative age-graded influences* are biological (such as the menopause) and social changes (such as marriage and parenting) that normally occur at fairly predictable ages
2. *normative history-graded influences* are historical events that affect whole generations or *cohorts* at about the same time (examples include wars, recessions and epidemics)
3. *non-normative influences* are idiosyncratic transitions, such as divorce, unemployment, and illness.

Levinson's (1986) term *marker events* refers to age-graded and non-normative influences. Others prefer the term *critical life events* to describe such influences, although it's probably more accurate to describe them as *processes*. Some critical life events, such as divorce, unemployment, and bereavement, can occur at any time during adulthood (bereavement is discussed in Chapter 39). Others occur late in adulthood, such as retirement (also discussed in Chapter 39). Yet others tend to happen early in adulthood, such as marriage (or partnering) and parenting.

ASK YOURSELF...
- What do you understand by the term adulthood?
- What does it mean to be an adult?

ERIKSON'S THEORY: ACHIEVING INTIMACY AND GENERATIVITY

As we saw in Chapter 37, Erikson believes that human development occurs through a sequence of *psychosocial stages*. As far as early and middle adulthood are concerned, Erikson described two primary developmental crises (the sixth and seventh of his psychosocial stages: see Table 38.1, page 650).

The first involves the establishment of *intimacy,* which is a criterion of having attained the psychosocial state of adulthood. By intimacy, Erikson means the ability to form close, meaningful relationships with others without 'the fear of losing oneself in the process' (Elkind, 1970). Erikson believed that a prerequisite for intimacy was the attainment of *identity* (the reconciliation of all our various roles into one enduring and stable personality: see Chapter 37, pages 640-644). Identity is necessary because we cannot know what it means to love someone and seek to share our life with them until we know who we are, and what we want to do with our lives. Thus, genuine intimacy requires us to give up some of our sense of separateness, and we must each have a firm identity to do this.

Intimacy needn't involve sexuality. Since intimacy refers to the essential ability to relate our deepest hopes and fears to another person, and in turn to accept another's need for intimacy, it describes the relationship between friends just as much as that between sexual partners (Dacey, 1982). By sharing ourselves with others, our personal identity becomes fully realised and consolidated. Erikson believed that if a sense of intimacy isn't established with friends or a partner, then *isolation* (a sense of being alone without anyone to share with or care for) would result. We normally achieve intimacy in young adulthood (our twenties and thirties), after which we enter middle age (our forties and fifties). This involves the attainment of *generativity,* the positive outcome of the second developmental crisis.

Box 38.1 Generativity

- The central task of the middle years of adulthood is to determine life's purpose or goal, and to focus on achieving aims and contributing to the wellbeing of others (particularly children).
- *Generativity* means being concerned with others beyond the immediate family, such as future generations and the nature of the society and world in which those future generations will live. As well as being displayed by parents, generativity is shown by anyone actively concerned with the welfare of young people and in making the world a better place for them to live and work.
- People who successfully resolve this developmental crisis establish clear guidelines for their lives, and are generally productive and happy within this directive framework. Failure to attain generativity leads to *stagnation,* in which people become preoccupied with their personal needs and comforts. They indulge themselves as if they were their own (or another's) only child.

Evaluation of Erikson's theory

- The sequence from identity to intimacy may not accurately reflect present-day realities. In recent years, the trend has been for adults to live together before marrying, so they tend to marry later in life than people did in the past (see below, pages 656-657). Many people struggle with identity issues (such as career choice) at the same time as dealing with intimacy issues.
- Additionally, some evidence suggests that females achieve intimacy *before* 'occupational identity'. The typical life course of women involves passing directly into a stage of intimacy without having achieved personal identity. Sangiuliano (1978) argues that most women submerge their identities into those of their partners, and only in mid-life do they emerge from this and search for separate identities and full independence. There's also a possible interaction between gender and *social class.* For example, working-class men

Table 38.1 Comparison between Erikson's and Freud's stages of development (based on Thomas, 1985; Erikson, 1950)

No. of stage	Name of stage (psychosocial crisis)	Psychosocial modalities (dominant modes of being and acting)	Radius of significant relationships	Human virtues (qualities of strength)	Freud's psychosexual stages	Approx. ages
1	Basic trust vs basic mistrust	To get. To give in return	Mother or mother-figure	Hope	Oral	0–1
2	Autonomy vs shame and doubt	To hold on. To let go	Parents	Willpower	Anal	1–3
3	Initiative vs guilt	To make (going after). To 'make like' (playing)	Basic family	Purpose	Phallic	3–6
4	Industry vs inferiority	To make things (completing). To make things together	Neighbourhood and school	Competence	Latency	6–12
5	Identity vs role confusion	To be oneself (or not to be). To share being oneself	Peer groups and outgroups. Models of leadership	Fidelity	Genital	12–18
6	Intimacy vs isolation	To lose and find oneself in another	Partners in friendship, sex, competition, co-operation	Love		20s
7	Generativity vs stagnation	To make be. To take care of	Divided labour and shared household	Care		Late 20s–50s
8	Ego integrity vs despair	To be, through having been. To face not being	'Humankind', 'my kind'	Wisdom		50s and beyond

see early marriage as a 'good' life pattern: early adulthood is a time for 'settling down', having a family and maintaining a steady job. By contrast, middle-class men and women see early adulthood as a time for exploration, in which different occupations are tried. Marriage tends to occur after this, and 'settling down' doesn't usually take place before 30 (Neugarten, 1975). There's also evidence of an interaction between gender, race and culture (see Cross-Cultural Study 38.1, below).

◎ Another example of how Erikson's stages may not apply to everyone is the case of 'baby fathers', the name given to young black men who have children with a number of women and wear this as a 'badge of honour' (Alibhai-Brown, 2000).

CROSS-CULTURAL STUDY 38.1

Intimacy and identity (Ochse & Plug, 1986)

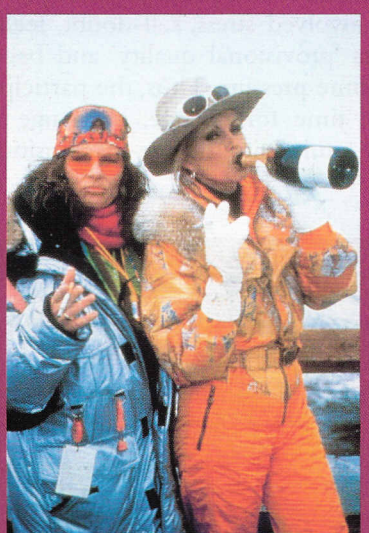
- Ochse and Plug studied over 1800 South African black and white men and women. Their findings raise questions about both the timing of particular stages and the exact sequence of the developmental tasks involved.
- For example, amongst whites, 25–39-year-old women appeared to develop a sense of identity *before* men. This may be because developing a true sense of intimacy must *precede* a sense of identity (not vice versa, as Erikson claimed). According to Price & Crapo (1999):

  It is quite feasible that by sharing and risking themselves in close relationships, people may learn to know themselves, to reconcile their conception of themselves with the community recognition of them, and to develop a sense of mutuality with their community.

  Not until this process is complete can a sense of identity be achieved.
- Due to prevailing social conditions in South Africa (including minority status, high poverty rates and fragmented living conditions), black women had a difficult time achieving a sense of intimacy and hence of identity. Black men also didn't achieve a sense of identity until late in life. In turn, this adversely affected black women, who still experienced a lack of self-definition, intimacy and wellbeing far into middle age:

It appears that the experience of the 'adult years' was one thing for whites and something quite different for blacks. As social conditions change in South Africa, whole groups of blacks may expect to experience a completely different psychological development than they would have under apartheid ... (Price & Crapo, 1999)

- Erikson's psychosocial stages were meant to be *universal,* applying to both genders in all cultures. However, he acknowledged that the sequence of stages is different for a woman, who suspends her identity as she prepares to attract the man who will marry her. Men achieve identity before achieving intimacy with sexual partners, whereas for women, Erikson's developmental crises appear to be fused. As Gilligan (1982) has observed:



The female comes to know herself as she is known, through relationships with others.

- All the above evidence suggests that it's almost certainly impossible to describe universal stages for adults. Moreover, as we saw in Chapter 37, there's evidence of a growing prolongation of adolescence.

Box 38.2 Perpetual adolescence

- According to Sheehy (1996), while childhood is ending earlier, adults are prolonging adolescence into their thirties. Indeed, many people aren't acknowledging maturity until they reach 40. Sheehy suggests that:

  Adolescence is now prolonged for the middle classes until the end of their twenties, and for blue-collar men and women until their mid-twenties, as more young adults live at home longer. True adulthood does not begin until 30. Most Baby Boomers, born after World War II, do not feel fully 'grown up' until they are in their forties, and even then they resist ...

- Beaumont (1996) argues that we've evolved into a generation of 'Peter Pans', stuck in adolescence:

  You see them in Hyde Park – thirty- and forty-somethings on rollerblades and skateboards, hanging out at Glastonbury or discussing the merits of Oasis versus Blur at dinner parties.

- The fictional models of this 'new generation' are Gary and Tony from the BBC TV programme *Men Behaving Badly,* and Patsy and Eddy from *Absolutely Fabulous.* Real-life examples of 'Peter Pans' include Cliff Richard, Richard Branson and Mick Jagger.

- According to Orbach (in Beaumont, 1996), one problem created by adults who refuse to grow up is their own parenting. Unable to look up to figures of authority themselves, they feel a sense of loss and look to their own children for emotional sustenance in a curious role reversal (see Chapter 32).

LEVINSON *ET AL.*'S 'SEASONS OF A MAN'S LIFE'

Perhaps the most systematic study of personality and life changes in adulthood began in 1969, when Levinson *et al.* interviewed 40 men aged 35 to 45. Transcripts were made of the five to ten tape-recorded interviews that each participant gave over several months. Levinson *et al.* looked at how adulthood is actually *experienced.*

In *The Seasons of a Man's Life,* Levinson *et al.* (1978) advanced a *life-structure theory,* defining life structure as the

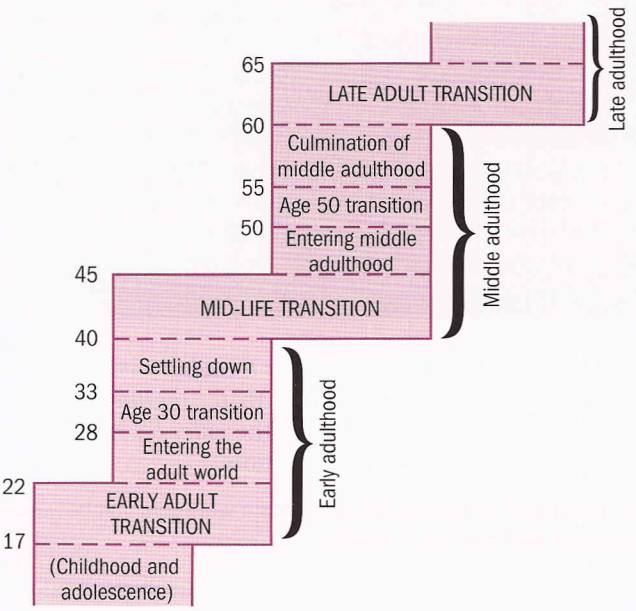


Figure 38.1 Levinson *et al.*'s theory of adult development. The life cycle is divided into four major eras that overlap in the form of cross-era transitions (from Levinson *et al.*, 1978, *The Seasons of a Man's Life*. New York: A.A. Knopf, a division of Random House, Inc. Reprinted by permission of SLL/Sterling Lord Literistic, Inc. © 1975 by Daniel J. Levinson)

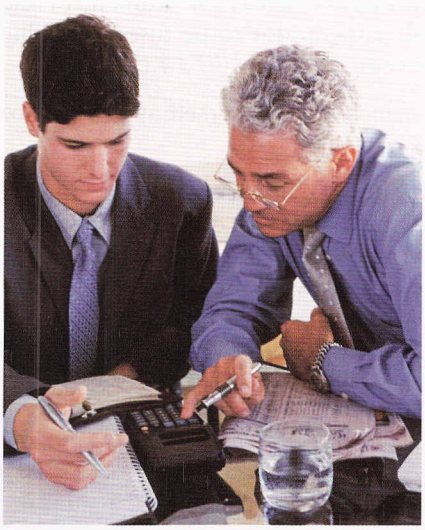
underlying pattern or design of a person's life at any given time. Life structure allows us to 'see how the self is in the world and how the world is in the self', and evolves through a series of *phases* or *periods* which give overall shape to the course of adult development. Adult development comprises a sequence of *eras* which overlap in the form of *cross-era transitions.* These last about five years, ending the outgoing era and initiating the incoming one. The four eras are pre-adulthood (age 0–22), early adulthood (17–45), middle adulthood (40–65), and late adulthood (60 onwards).

The phases or periods alternate between those that are stable (or *structure-building*) and transitional (or *structure-changing*). Although each phase involves biological, psychological and social adjustments, family and work roles are seen as central to the life structure at any time, and individual development is interwoven with changes in these roles.

The era of early adulthood

Early adult transition (17–22) is a developmental 'bridge' between adolescence and adulthood.

Box 38.3 Separation and attachment



- Two key themes of the early adult transition are *separation* and the formation of *attachments* to the adult world.
- *External separation* involves moving out of the family home, increasing financial independence, and entering more independent and responsible roles and living arrangements.
- *Internal separation* involves greater psychological distance from the family, less emotional dependence on the parents, and greater differentiation between the self and family. Although we separate from our parents, Levinson *et al.* argue that we never complete the process, which continues throughout life.
- *Attachment* involves exploring the world's possibilities, imagining ourselves as part of it, and identifying and establishing changes for living in the world before we become 'full members' of it.

Between ages 22 and 28, we *enter the adult world.* This is the first *structure-building* (rather than *structure-changing*) phase, and hence is referred to as the *entry life structure for early adulthood.* In it, we try to fashion:

> ... a provisional structure that provides a workable link between the valued self and adult society.

In the *novice phase,* we try to define ourselves as adults and live with the initial choices we make concerning jobs, relationships, lifestyles and values. However, we need to create a balance between 'keeping our options open' (which allows us to explore possibilities without being committed to a given course) and 'putting down roots' (or creating stable life structures).

Our decisions are made in the context of our *dreams:* the 'vague sense' we have of ourselves in the adult world and what we want to do with our lives. We must overcome disappointments and setbacks, and learn to accept and profit from successes, so that the dream's 'thread' doesn't get lost in the course of 'moving up the ladder' and revising the life structure. To help us in our efforts at self-definition, we look to *mentors,* older and more experienced others, for guidance and direction. Mentors can take a formal role in guiding, teaching, and helping novices to define their dreams. Alternatively, a mentor's role may be informal, providing an advisory and emotionally supportive function (as a parent does).

Mentoring

The age-30 transition (28–33) provides an opportunity to work on the flaws and limitations of the first life structure, and to create the basis for a more satisfactory structure that will complete the era of young adulthood. Most of Levinson *et al.*'s participants experienced *age-30 crises* which involved stress, self-doubt, feelings that life was losing its 'provisional quality' and becoming more serious, and time pressure. Thus, the participants saw this as being the time for change, if change was needed. However, for a minority the age-30 transition was crisis-free.

Box 38.4 Settling down

- The *settling down* (or *culminating life structure for early adulthood:* 33–40) *phase* represents consolidation of the second life structure. This involves a shift away from tentative choices regarding family and career towards a strong sense of commitment to a personal, familial, and occupational future.
- Paths for success in work and husband and father roles are mapped out and, instead of just beginning to find out

what's important and what our opinions are, we see ourselves as responsible adults.
- The settling down phase comprises two sub-stages: *early settling down* (33–36) and *becoming one's own man* (BOOM) (36–40). In the latter, men strive to advance and succeed in building better lives, improve and use their skills, be creative, and in general contribute to society.
- A man wants recognition and affirmation from society, but he also wants to be self-sufficient and free of social pressure and control. Although a 'boy–man' conflict may be produced, this can represent a step forward. This substage may also see him assume a mentor role for someone younger (see above).

The era of middle adulthood

ASK YOURSELF...
- What do you think is meant by the 'mid-life crisis'?
- Do you think it's a real phenomenon?

The *mid-life transition* (40–45) involves terminating one life structure, initiating another, and continuing the process of *individuation* started during the BOOM substage. This is a time of soul-searching, questioning, and assessing the real meaning of the life structure's achievement. It's sometimes referred to as the *mid-life crisis,* although Levinson *et al.* didn't actually use this term. For some people, the change is gradual and fairly painless. But for others, it's full of uncertainties.

The crisis stems from unconscious tensions between attachment and separation, the resurfacing of the need to be creative (which is often repressed in order to achieve a career), and retrospective comparisons between dreams and life's reality.

Most participants in Levinson *et al.*'s study hadn't reached age 45. Following interviews two years after the main study was concluded, some were chosen for more extensive study. But the evidence for the remaining phases is much less detailed than for the earlier ones.

In *entering middle adulthood* (or *early life structure for middle adulthood:* 45–50), we've resolved (more or less satisfactorily) whether what we've committed ourselves to really is worthwhile. It's again necessary to make choices regarding a new life structure. Sometimes, these choices are defined by *marker events* such as divorce, illness, occupational change or the death of a loved one. However, the choices may also be influenced by less obvious but significant changes, such as shifts in the enthusiasm for work or in the quality of marriage. As before, the resulting life structure varies in how satisfying it is and how connected it is to the self. It may not be intrinsically happy and fulfilling. The restructuring consists of many steps, and there may be setbacks in which options have to be abandoned ('back to the drawing board').

Is there a 'mid-life crisis'?

Just as the 'identity crisis' is part of the popular stereotype of adolescence (see Chapter 37), Levinson *et al.* have helped to make the 'mid-life crisis' part of the common-sense understanding of adult development. Like Erikson, Levinson *et al.* see crisis as *inevitable.* As they note:

> It is not possible to get through middle adulthood without having at least a moderate crisis in either the mid-life transition or the age-50 transition.

They also see crisis as *necessary.* If we don't engage in soul searching, we'll:

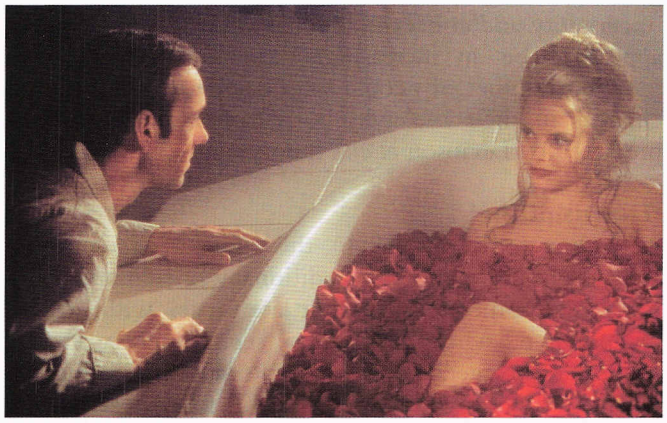
> ... pay the price in a later developmental crisis or in a progressive withering of the self and a life structure minimally connected to the self.

The view that crisis is both inevitable and necessary (or *normative,* to use Erikson's term) is controversial. People of all ages suffer occasional depression, self-doubt, sexual uncertainty, and concerns about the future. Indeed, there appear to be an increasingly wide age range and a growing number of people who decide to make radical changes in their life-style, both earlier and later than predicted by Levinson *et al.*'s theory.

'Downshifting'

According to Tredre (1996), the concept of a mid-life crisis is too narrow in that traditionally, or stereotypically, it refers to someone in his/her late forties, with grown-up children, who gives up a secure and well-paid 'respectable' career, and moves to a small market town or village in order to enjoy a less stressful, more peaceful and generally better quality of life. We need to spread the net wider nowadays, and think in terms of early-, mid- and late-life crises: people of all age groups and walks of life are 'feeling the itch'.

Downshifting refers to voluntarily opting out of a pressurised career and interminably long hours in the office, and often involves giving up an exceptionally well-paid job in a high-profile industry in the pursuit of a more fulfilling way of life. Tredre identifies a number of possible reasons for downshifting, including anti-urbanism (fuelled by concerns over urban pollution), crime, violence and increasing job insecurity.



Box 38.5 Identity crisis and the life cycle

- Marcia (1998) also believes that the concept of a mid-life crisis is misleading and too narrow. He argues that 'adolescing' (making decisions about one's identity) occurs *throughout* the lifespan, whenever we review or reorganise our lives. At the very least, we might expect identity crises to accompany (in Erikson's terms) intimacy–isolation, generativity–stagnation, and integrity–despair (see Chapter 39).

- Just as puberty and other changes in early adolescence disrupt the partial identities of childhood, so the demands of intimacy require a reformulation of the initial identity achieved at late adolescence. Similarly, the generative, care-giving requirements of middle age differ from those of being with an intimate partner. The virtues of fidelity, love and care (see Table 38.1), which derive from positive resolution of young and middle adulthood, don't emerge without a struggle. According to Marcia (1998):

  Periods of adolescing are normal, expectable components of life cycle growth.

- However, while crises aren't limited to specific times in our lives, those associated with middle (and old) age are especially difficult.

Kevin Spacey as a man experiencing a mid-life crisis in *American Beauty*. This becomes focused (literally) on his daughter's friend, played by Mena Suvari

ASK YOURSELF...
- Who's 'more right', Levinson *et al.* or Marcia?
- Who would you *prefer* to be right?

Durkin (1995) notes that a large proportion of middle-aged people actually feel *more* positive about this phase of life than earlier ones, with only 10 per cent reporting feeling as though they'd experienced a crisis. For Durkin, the mid-life crisis isn't as universal as Levinson *et al.* suggest, and the time and extent to which we experience uncomfortable self-assessments vary as a function of several factors (such as personality). Although the evidence is sparse, it appears that going through middle age in a relatively peaceful and untroubled way is actually a *favourable* indicator of future development, that is, a lack of emotional disturbance predicts *better* rather than poorer functioning in later life (Rutter & Rutter, 1992).

Two other components of the mid-life crisis are much less controversial.

1. A wide range of adaptations in the life pattern. Some of these stem from role changes that produce fairly drastic consequences, such as divorce, remarriage, a major occupational change, redundancy, or serious illness. Others are more subtle, and include the ageing and likely death of parents, the new role of grandparent, and the sense of loss which sometimes occurs when children have all moved away from the family home (*empty-nest distress*).
2. Significant change in the *internal* aspects of life structures, which occurs regardless of external events. This involves reappraising achievements and remaining ambitions, especially those to do with work and relationships with our sexual partners. A fundamental development at this time is the realisation that the final authority for life rests with us. (This is similar to Gould's, 1978, 1980, theory: see below.)

CRITICAL DISCUSSION 38.1 : Is there a male menopause?

A recent World Health Organization conference on the ageing male concluded that there's definitely a male biological andropause, and that men also suffer from osteoporosis (as do women). There's also an increased risk of heart attack from declining testosterone levels.

The critical measure, though, is 'bio-available' testosterone. As testosterone declines, sex hormone binding globulin (SHBG) increases. SHBG traps much of the testosterone that's still circulating and prevents it from affecting the body's tissues. What's left over ('bioavailable') does the beneficial work, but this is what radically declines from about the age of 45. Hence, the case for testosterone (male hormone) replacement therapy.

But even more critical may be a second hormone, DHEA (a steroid produced by the adrenals), levels of which decline dramatically in the early thirties. DHEA elevates mood, cognition, immune response, promotes lean body mass, increases sexual drive, reduces fatigue, and prevents hardening of the arteries. Above all, it appears to improve brain function and repair memory loss.
(Based on Hodson, 2000)

The seasons of a woman's life

Levinson *et al.*'s research was carried out on an all-male sample. In *The Seasons of a Woman's Life* (1997), Levinson and Levinson presented their findings for 45 women (aged 35 to 45), comprising 15 homemakers (full-time housewives/mothers), 15 businesswomen and 15 academics. The broad pattern of developmental periods based on the original male sample was confirmed. But men and women have been shown to differ in terms of their *dreams*.

Box 38.6 Women's dreams and 'gender splitting'

- Levinson (1986) argues that a *'gender-splitting'* phenomenon occurs in adult development. Men have fairly unified visions of their futures, which tend to be focused on their careers. But women have 'dreams' which are more likely to be split between a career and marriage.
- This was certainly true of academics and business-women, although the former were less ambitious and more likely to forego a career, whereas the latter wanted to maintain their careers but at a reduced level. Only the homemakers had unified dreams (to be full-time wives and mothers, as their own mothers had been).
- The family plays a 'supportive' role for men. Women's dreams were constructed around their relationships with their husbands and families, which subordinated their personal needs. So, part of *her* dream is *his* success. For Durkin (1995), this difference in women's and men's priorities may put women at greater risk:

  ... of disappointment and developmental tension as their investment in others' goals conflict with their personal needs.

- Women who give marriage and motherhood top priority in their twenties tend to develop more individualistic goals for their thirties. However, those who are career-oriented early on in adulthood tend to focus on marriage and family concerns later.
- Generally, the transitory instability of the early thirties lasts longer for women than for men, and 'settling down' is much less clear-cut. Trying to integrate career and marriage/family responsibilities is very difficult for most women, who experience greater conflicts than their husbands are likely to.

Gender-splitting is relevant to discussion of marriage/partnering and parenthood. The changing roles of women in paid employment and of men in the home are discussed later in the chapter (see pages 660–663).

THE VALIDITY OF STAGE THEORIES OF ADULT DEVELOPMENT

ASK YOURSELF...

- Do you think it's appropriate to describe adulthood in terms of distinct stages?

- Erikson's and Levinson *et al.*'s theories of adult development emphasise a 'ladder-like' progression through an inevitable and universal series of stages/phases. But this view of adult development as 'stage-like' has been criticised on the grounds that it underestimates the degree of *individual variability* (Rutter & Rutter, 1992). Many members of the mainstream working-class population don't grow or change in systematic ways. Instead, they show many rapid fluctuations, depending on things like relationships, work demands and other life stresses that are taking place (Craig, 1992).
- Stage theories also imply a *discontinuity* of development. But many psychologists believe there's also considerable *continuity* of personality during adult life.
- Current views of adult development stress the transitions and milestones that mark adult life, rather than a rigid developmental sequence (Baltes, 1983, Schlossberg, 1984). This is commonly referred to as the *life-events approach*. Yet, despite the growing unpredictability of changes in adult life, most people still unconsciously evaluate their transitions according to a *social clock*, which determines whether they're 'on time' with respect to particular life events (such as getting married: Schlossberg *et al.*, 1978). If they're 'off time', either early or late, they're *age-deviant*. Like other types of deviancy, this can result in social penalties, such as amusement, pity or rejection.
- While all cultures have social clocks that define the 'right' time to marry, begin work, have children, and so on, these clocks vary greatly *between* cultures (Wade & Tavris, 1999). Craig (1992) sees changes in adult thought, behaviour and personality as being less a result of chronological age or specific biological changes, and more a result of personal, social and cultural events or forces. Because of the sheer diversity of experiences in an adult's life, Craig doesn't believe it's possible to describe major 'milestones' that will apply to nearly everyone.

CRITICAL DISCUSSION 38.2 What is an adult: re-setting the social clock

- Just as social clocks are 'set' at different times in different cultures for different life changes, in western societies the clock becomes 're-set' over time.
- For example, 40 to 50 years ago, a stable job and income could be achieved (by men) by age 21, and so this was seen as the time to 'settle down'. If a woman wasn't married by the time she was 25, she was 'on the shelf', and if still single by 29, she was an 'old maid'.
- Common beliefs about the appropriate age for child-bearing put pressure on women to become mothers by their early twenties, and pregnancy after 26 was seen as 'late' (Apter, 2001). These patterns are drastically different now.
- As both cause and effect of these changes, our whole understanding of what it means to be adult is changing. In *The Myth of Maturity* (2001), Apter argues that it's taking young people far longer to achieve adult status than it used to. She refers to 18–24-year-olds as 'thresholders', because they're only *on the brink* of achieving self-sufficiency and autonomy (commonly cited adult qualities). They're like 'apprentices to adulthood'.
- A total of 58 per cent of 22–24-year-olds and 30 per cent of 24–30-year-olds (still) live with their parents. Leaving

home isn't a single event, but a prolonged *process:* 40 per cent of female and 50 per cent of male thresholders who leave home will subsequently return.

- There are a thousand different routes from adolescence to adulthood, each involving uncertainty and risk (Apter, 2001).

ASK YOURSELF...

- Would you describe yourself as a thresholder?
- Are many of your peers thresholders?

GOULD'S THEORY OF THE EVOLUTION OF ADULT-CONSCIOUSNESS

Whereas Levinson *et al.* discussed adult development in terms of evolving life structures, Gould (1978, 1980) prefers to talk about the *evolution of adult consciousness* which occurs when:

... we release ourselves from the constraints and ties of childhood consciousness.

Gould sees the thrust of adult development as being towards the realisation and acceptance of ourselves as creators of our own lives, and away from the assumption that the rules and standards of childhood determine our destinies. We have to free ourselves of the *illusion of absolute safety,* an illusion which dominated childhood. This involves transformations, giving up the security of the past to form our own ideas. We have to replace the concept of parental dependency with a sense of autonomy, or owning ourselves. But this is difficult, because dependency on parents is a normal feature of childhood. Indeed, without it, childhood would be very difficult. As well as shedding childhood consciousness, Gould believes that our *sense of time* also changes.

Box 38.7 Our changing sense of time

- Up until age 18 or so, we feel both protected and constrained by our parents, and never quite believe that we'll escape the 'family world'. This is like being in a timeless capsule in which 'the future is a fantasy space that may possibly not exist'. But we begin to glimpse an endless future and see an infinite amount of time ahead of us.
- In our twenties, we become confident about being separated from the family. However, we haven't yet formed early adult life structures. Gould (1980) puts it like this:

  Because of all the new decisions and novel experiences that come with setting up new adult enterprises, our time sense, when we're being successful, is one of movement along a chosen path that leads linearly to some obscure prize decades in the future. There is plenty of time, but we're still in a hurry once we've developed a clearer, often stereotyped, picture of where we want to be by then.

- At the end of our twenties, our sense of time incorporates our adult past as well as future. The future is neither infinite nor linear, and we must choose between different options because there isn't time to take them all.
- From our mid-thirties to mid-forties, we develop a sense of urgency and that time is running out. We also become aware of our own mortality which, once attained, is never far from our consciousness. How we spend our time becomes a matter of great importance. Additionally, we begin to question whether our 'prize' (freedom from restrictions by those who have formed us – our parents) either exists or, if it does, whether it's been worth it (cf. Levinson *et al.*'s 'dream').

MARRIAGE

ASK YOURSELF...

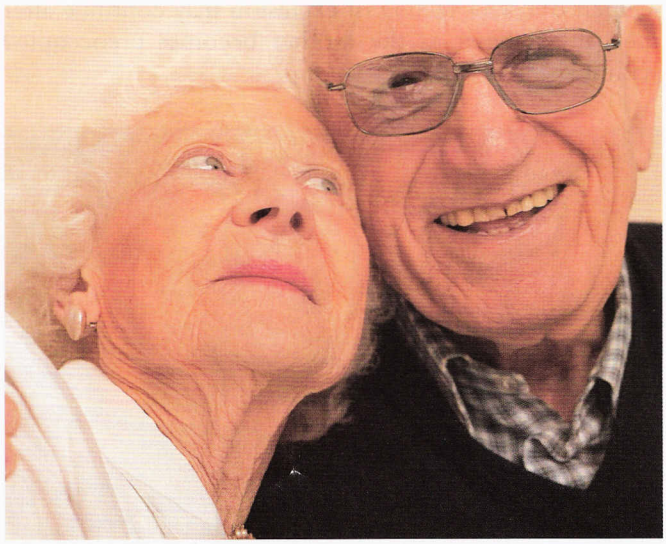
- Identify some arguments for and against marriage, as compared with 'living together' (cohabitation).

Since over 90 per cent of adults in western countries marry at least once, marriage is an example of a *normative age-graded influence* (see *Introduction and overview*). Marriage is an important transition for young adults, because it involves a lasting personal commitment to another person (and, so is a means of achieving Erikson's *intimacy*), financial responsibilities and, perhaps, family responsibilities.

Marriage and preparation for marriage can be very stressful. Davies (1956) identified mental disorders occurring for the first time in those who were engaged to be married. Typically, these were anxiety and depression, which usually began in connection with an event that hinged on the wedding date (such as booking the reception). Since the disorders improved when the engagement was broken off or the wedding took place, Davies concluded that it was the *decision* to make the commitment that was important, rather than the act of getting married itself.

Cohabitation

Couples who live together (or *cohabit*) before marriage are *more* likely to divorce later, and be less satisfied with their marriages, than those who marry without having cohabited. Also, about 40 per cent of couples who cohabit don't marry. While this suggests that cohabitation may prevent some divorces, cohabitees who do marry are more likely to divorce.



ASK YOURSELF...

- Why do you think cohabitees who marry are more likely to divorce?

According to Bee (1994), this is because people who choose to cohabit are different from those who choose not to. As a group, cohabitees seem to be more willing to flout tradition in many ways (such as being less religious and disagreeing that one should stay with a marriage partner no matter what). Those who don't cohabit include a large proportion of 'more traditional' people.

The benefits of marriage

It's long been recognised that mortality is affected by marital status. Married people tend to live longer than unmarried people, are happier, healthier and have lower rates of various mental disorders than the single, widowed or divorced. The greater mortality of the unmarried relative to the married has generally been increasing over the past two to three decades, and it seems that divorced (and widowed) people in their 20s and 30s have particularly high risks of dying compared with other people of the same age (Cramer, 1995).

Being happily married protects against mental and physical illness

ASK YOURSELF...

- Why – or how – might marriage produce these beneficial effects? Look back at your answers to the previous 'Ask Yourself' box. Did any of the arguments for marriage include its psychological/emotional benefits?
- Are there any reasons for believing that either men or women derive greater benefits?

CRITICAL DISCUSSION 38.3 Do men get more from marriage than women?

- Bee (1994) argues that the greatest beneficiaries of marriage are men, partly because they're less likely than women to have close confidants outside marriage, and partly because wives provide more emotional warmth and support for husbands than husbands do for wives.
- Marriage is less obviously psychologically protective for women, not because a confiding and harmonious relationship is any less important for them (indeed, if anything it's more important), but because:
  (a) many marriages don't provide such relationships, and
  (b) other consequences of marriage differ between the sexes.
  (The 'advantage' of marriage for men is reflected in the higher rates of men's re-marriage following divorce: see text below.)
- Although our attitudes towards education and women's careers have changed, Rutter & Rutter (1992), echoing Levinson's concept of 'gender-splitting' (see Box 38.6), have proposed that:

  The potential benefits of a harmonious relationship may, for a woman, be counterbalanced by the stresses involved in giving up a job or in being handicapped in a career progression or promotion through having to combine a career and parenthood.

This is discussed further on pages 659–663.

DIVORCE

Although divorce rates in the USA have shown a modest decline since 1979, over 45 per cent of marriages still end in divorce (Simons, 1996). The average marriage in the USA lasts seven years; nine in the UK (Bedell, 2002). Divorce rates are highest during the first five years of marriage, and then peak again after couples have been married for 15–25 years (Turnbull, 1995).

In 1996, there were about 1,150,000 divorces in the USA, involving over one million children, 84 per cent of whom live with their mothers in single-parent homes. But this is usually only temporary, since 65 per cent of women and over 75 per cent of men remarry, and 40 per cent of all marriages are second-time-arounders (Groskop, 2004). Rates of cohabitation are high in those who don't remarry. Divorce rates are even higher in remarriages than first marriages. Only 65 per cent of children in the UK live with *both* natural parents, and one in ten have a step-parent (1,284,000 children: Groskop, 2004).

So, in recent decades, the structure and stability of families in western societies have undergone considerable changes. An increasing number of adults live in subsequent cohabiting or remarried relationships and, in turn, these changes have led to a marked rise in the number of

children living in step-family situations (Nicholson *et al.*, 1999: see page 663).

National statistics conceal important racial and ethnic differences. For example, compared with non-Hispanic Whites, African-Americans wait longer before marrying and are less likely to marry, but are also more likely to separate and divorce and to remain separated without a legal divorce. They're also less likely to remarry (Hetherington & Stanley-Hagan, 1999).

The stresses and benefits of divorce

Divorce is a *stressor* for both men and women (see Chapter 12), since it involves the loss of one's major attachment figure and source of emotional support. But men appear to experience more stress than women, which is perhaps not altogether surprising given the greater benefits to men of marriage (see above).

According to Woollett and Fuller (in Cooper, 1996), mothers who've been through a divorce often report experiencing a sense of achievement in their day-to-day activities and a feeling of 'a job well done'. This is because they use their experiences of divorce in a positive way to 'galvanise' them into taking charge of their lives. According to Woollett:

> When the marriage breaks down, the mother is thrown into all sorts of things that are unfamiliar. There are new areas, new decisions, and she is forced to cope ...

However, Lewis (in Cooper, 1996) warns that:

> We must be careful about thinking about the positive changes [divorced women report] because we are always comparing a positive change against the negative feeling that went before. The positive is only relative.

PARENTHOOD

For most people, parenthood and child-rearing represent key transitions. According to Bee (1994), 90 per cent of adults will become parents, mostly in their twenties and thirties. But parenthood varies in meaning and impact more than any other life transition. It may occur at any time from adolescence to middle age, and for some men, may even occur in late adulthood! Parenthood may also be planned or unplanned, wanted or unwanted, and there are many motives for having children.

Traditionally, parenthood is the domain of the married couple. However, it may involve a single woman, a homosexual couple (see page 664), a cohabiting couple or couples who adopt or foster children. Increasingly, in recent decades there's been a marked rise in the number of teenage pregnancies (see Chapter 37), and even more recently, the phenomenon of 'minimal parenting' (as in donor insemination: see Chapter 32).

Equally, though, the increasing importance of work careers for women has also led to more and more couples postponing starting a family, so that the woman can become better established in her career (see Critical Discussion 38.4). For example, women's average age at the birth of their first child was almost 30 in 2003 (compared with 23 in the 1960s: Groskop, 2004). Consequently, there's a new class of middle-aged parents with young children (Turnbull, 1995).

ASK YOURSELF...

- Assuming that they're planned, why do people have children? What are their motives ?
- Is it 'natural' (at least for women) to want children?

Parenthood brings with it many psychological adaptations. For example, many women worry that their baby may be abnormal, about the changes in their body, and how well they'll cope with motherhood. Another concern is how the relationship with their husband or partner will be affected. While pregnancy brings many couples closer together, most men take longer than women to become emotionally involved in it – and some feel left out. This feeling of exclusion may continue after the baby is born, as the mother becomes preoccupied with it.

Being at the birth of his child can help counteract a father's feelings of being excluded during the pregnancy – and afterwards. It can also help him to form an emotional bond with the baby

Marital satisfaction tends to be highest before children arrive. It then drops and remains relatively low as long as there are dependent children in the home. Finally, it rises again during the 'post-parental' and retirement stages. For new parents, the roles of parent and spouse are at least partially incompatible. New parents report having less time for each other, whether it be conversing, having sex, being affectionate, or carrying out routine chores that used to be done together (Bee, 1994).

Parents are, of course, attachment figures for their dependent children. Unlike the relationship with a partner, the relationship with a child is *asymmetrical* (the child isn't an attachment figure for its parents: see Chapter 32). This new form of responsibility can be very stressful, and has implications for how parents adapt to these new role demands, and the quality of their interactions with the child (Durkin, 1995). An unhappy couple may stay together not just 'for the kids' sake', but because the parental role has sufficient meaning and value for each partner to outweigh the dissatisfaction with their marriage (Levinson *et al.*, 1978).

Box 38.8 Empty nest or crowded nest: which is more distressing?

- Regarding *empty-nest distress*, most parents *don't* find their children's departure from home to be a distressing time (Durkin, 1995). Indeed, many report that the end of child-rearing responsibilities is a 'liberating experience', and they welcome new opportunities for closer relationships with their partners, personal fulfilment through work, a return to education, and so on. The extent to which women report empty-nest distress may be *cohort-related*, that is, it may be more typical of women who reached maturity during historical periods when traditional roles were stressed (Durkin, 1995).
- The *crowded nest* (Datan *et al.*, 1987) can, however, be a source of stress. This occurs when grown-up children opt not to leave home, which defies the demands of the 'social clock' established by preceding generations. As we saw in Critical Discussion 38.2, middle-aged parents are increasingly sharing their homes with their thresh-older children (see Figure 38.2).

Womanhood and motherhood

According to Kremer (1998), in the post-industrial/post-modern world of the twenty-first century we're still influenced by beliefs and attitudes regarding work and the sexes (or 'gendered employment profiles') inherited from an earlier time. For example, the *motherhood mystique/mandate* refers to the belief that women are born and reared to be, first and foremost, mothers (while the 'fatherhood mandate' is hardly, if ever, mentioned: see Chapter 32). Another example is the stereotype of men as inherently more committed to work than women, whose attitudes towards it are less positive than men's.

The motherhood mandate has at least three important implications.

1. Motherhood is 'natural'. Berryman (in Lacey, 1998) maintains that motherhood is still seen as synonymous with womanhood:

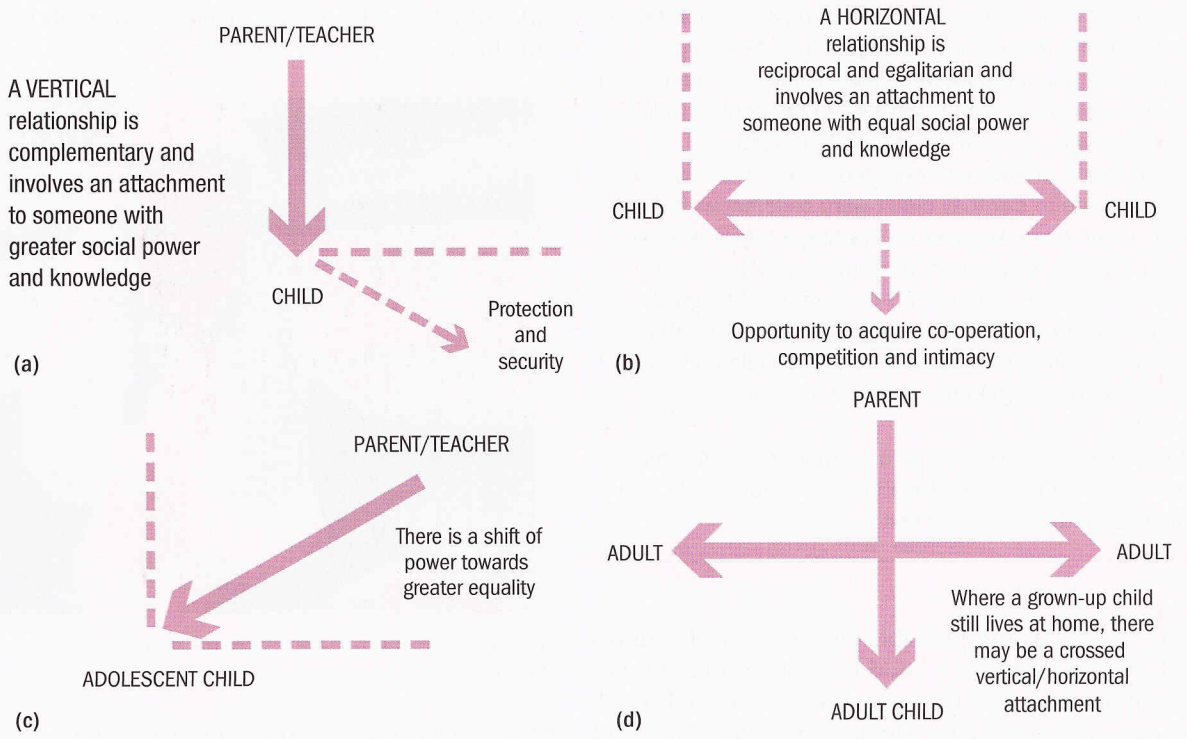


Figure 38.2 Different kinds of relationships based on Hartup's (1989) distinction between vertical and horizontal relationships. While (a) and (b) are clear-cut in terms of this distinction, (c) involves a change from vertical to horizontal, while (d) involves both dimensions simultaneously. Both (c) and (d) may involve conflict – but for different reasons

Parenthood is seen as a central, key role in women's lives in a way that it isn't for men. Women who don't become mothers are seen as psychologically inadequate – wanting in some way. But there is plenty of evidence that motherhood doesn't come naturally to all women; it is a skill that many women have to learn.

For example, Berryman maintains that, because smaller families and fewer siblings are now the norm, many women today have little experience of children when they start their own families – and the reality can come as a shock. This belief that mothering comes 'naturally' is so deep-rooted that women who don't bond immediately with their babies feel inadequate or guilty, or perhaps both. However, there are indications that attitudes towards having children are changing.

CRITICAL DISCUSSION 38.4 Do people still want to become parents?

- According to Jones (1995), 20 per cent of women in the UK born between 1960 and 1990 are unlikely ever to become mothers. They're likely to be well-educated, middle-class women, not necessarily pursuing a career, but realising that 'it's OK to go through life without having children' (Root Cartwright, in charge of the British Organisation of Non-Parents (BON)).
- Norton (1999) cites a market research survey conducted by Mintel (the *Pre-Family Lifestyles Report*, 1999), involving almost 700 20–34-year-olds without children. It found that more women than men thought it important to be financially secure and established in their careers before starting a family. More significantly, 25 per cent of women, compared with less than 20 per cent of men, saw their work as a career rather than a job.
- Married men and women were more likely than cohabiting couples to say they didn't want children, with those living alone being keenest on starting a family (85 per cent). Overall, 10 per cent of women said they were undecided about children; 25 per cent of the sample didn't want to assume the responsibility of parenthood, and only 3 per cent thought that having children early in adulthood outweighed the financial and career advantages.
- However, there's evidence of a growing trend for professional women to give up their careers in favour of full-time motherhood (see text below).

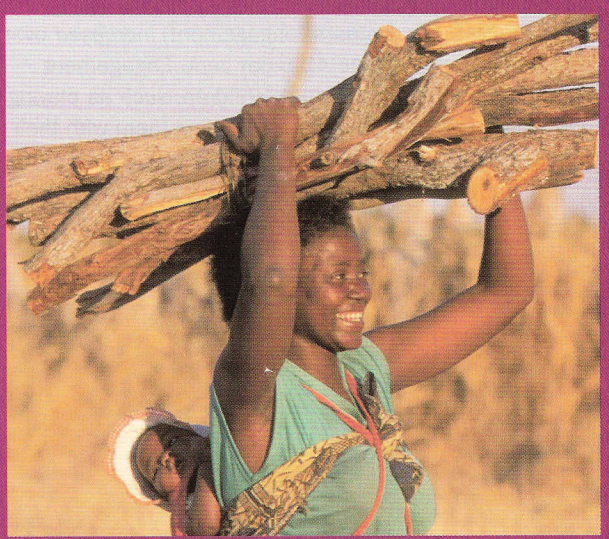
2. Most people would probably consider it to be 'unnatural' (or 'wicked') for a mother to leave her children, even if they're left in the care of their father, whom she believes will look after them better than she could herself. However, the number of absent mothers targeted by the Child Support Agency trebled between 1995 and 1998, with over 37,000 being approached to pay child maintenance. One in 20 absent parents is a woman (Lacey, 1998). Either there are a lot more 'unnatural' or 'wicked' women out there than was previously thought, or the motherhood mandate needs serious revision
3. It's 'unnatural' or simply 'wrong' for a mother of young children to go out to work. Related to this is the stereotype concerning women's attitudes towards paid employment. Is there any foundation for this stereotype?

The changing role of women in the workforce

Traditionally, men have been seen as dominating the primary employment sector, with their employment histories remaining unbroken from school to retirement. In contrast, women predominate in the secondary employment sector, which is typically unstable, offering poor career prospects and working conditions. There's also a dip or gap in paid employment associated with child-rearing during the mid-twenties to early thirties (Kremer, 1998).

However, at the end of the 1990s employment profiles for both genders were changing rapidly. Women comprised about half the workforce (although a far higher proportion were part-time than men), and mothers were less likely to leave work to care for young children. Yet women were still more likely than men to interrupt their careers, at least temporarily, to take care of children, while men rarely did (Craig, 1992; Nicholson, 1993). (This relates to the 'gender-splitting' phenomenon identified by Levinson (1986) and will be discussed further below.)

Cherie Blair: mother and barrister first, Prime Minister's wife second



Women's attitudes to paid employment

Kremer (1998) cites several surveys (conducted in the 1980s and 1990s) showing that, despite poorer working conditions, the overwhelming majority of working women prefer to be in paid employment. Additionally,

most of those not in work (especially those under 50) would prefer to be. When asked to rate the importance of various factors at work, the differences between men and women are few, and usually only involve clashes between work commitments and domestic responsibilities. Men and women also tend to agree about the motivation for working, such as money, stimulation, and feeling useful. Ironically (given their poorer working conditions), women consistently express higher job satisfaction (especially part-time workers and those working from home).

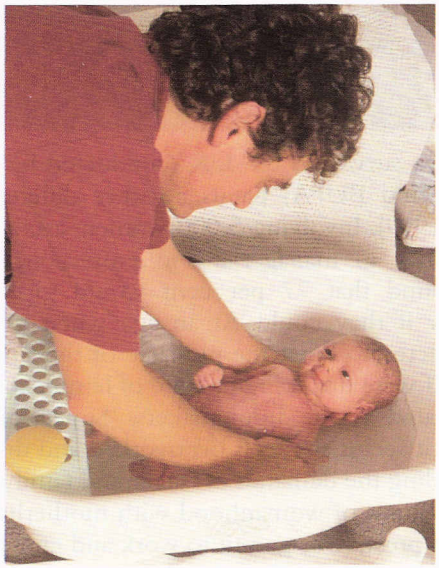
Box 38.9 Women, work and evolution

- According to Hrdy (1999), these findings should come as no surprise. Arguing from an *evolutionary perspective*, Hrdy claims that being ambitious is just as natural for a mother as breastfeeding. It's a fallacy to believe that mothers who go out to work are in conflict with their natural instincts. She argues that there's nothing new about working mothers: for most of human existence, and for millions of years before that, primate mothers have combined productive lives with reproduction. This combination of work and motherhood has always entailed trade-offs.

- What's new for modern mothers is the *compartmentalisation* of their productive and reproductive lives. The factories, laboratories and offices where women in post-industrial societies go to 'forage' are even less compatible with child care than jaguar-infested forests and distant groves of mongongo nuts.
- Hrdy is especially interested in the Pleistocene period, which extends from about 1.6 million years ago (when humans emerged from apes) to the invention of agriculture (about 10,000 years ago). It was during this period that many human instincts – including mothering – evolved through natural selection. Pleistocene woman would have striven for status and 'local clout' among her female peers. Ambition was just as much the driving force for women as for men, serving the Darwinian purpose of producing offspring who survived to adulthood.

However, a survey in the UK (conducted by *Top Santé* magazine and BUPA) paints a rather different picture (Brown, 1999). Involving 5,000 women, average age 36, the majority in managerial and professional jobs, the survey found that 77 per cent would give up work tomorrow if they could. At an age when most would have expected to be at the pinnacle of their professions, nearly half were dreaming of a life of leisure and almost a third wanted to be homemakers. 'Superwoman' may exist, but it seems she feels overworked and disillusioned from juggling the demands of career and family. Contrary to the equation of womanhood with motherhood, many feel under pressure to go out to work and raise families, as they feel that society doesn't value mothers who stay at home (Brown, 1999).

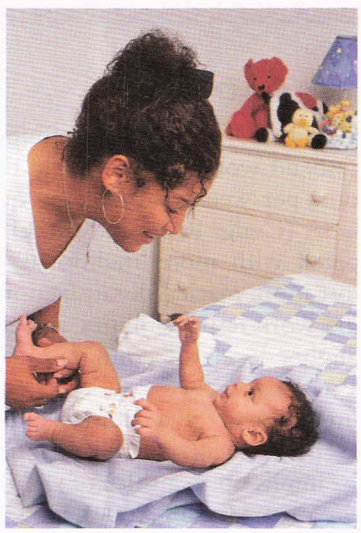
This trend was confirmed in a more recent *Top Santé* survey involving 2000 women (average age 38), which showed that two-thirds want to quit work because they're failing to manage successfully the competing demands of work and home (in Flett, 2004). Similarly, a recent report ('Choosing to be Different') from the Centre for Policy Studies states that there's a general rejection of the 1980s and 1990s work ethic. Women want to fit their work round their home life (and not vice-versa) (O'Kelly, 2004)



ASK YOURSELF...

- If women are having to juggle career and family, what does this tell us about the contribution of their husbands or partners?
- Does 'New Man' exist?

Does 'New Man' exist?



The phenomenon of 'dual-earner couples/marriages' (where the husband works full-time and the wife works at least 20 hours per week) has become quite common, both in the USA (Craig, 1992) and the UK (Nicholson, 1993). Compared with more 'traditional' couples, these husbands report more marital dissatisfaction and conflicts over family and work responsibilities, and the wives similarly report higher levels of conflict, as well as a very realistic work overload.

There's some evidence that domestic tasks (especially child care) are more evenly shared in some dual-earner families (for example, up to a third of all home child care is now done by men: Hinsliff, 2004). However, it's nearly always the woman who's still primarily responsible for both housework and child care, regardless of the age of the children and whether she works full- or part-time. Based on studies in eastern and western Europe, and

Fathers' involvement in childcare, though on the increase, is still not seen as 'men's work', but is more of a bonus – for child and father alike. Nor does it seem to reduce any of the mother's burden of responsibility

North and South America, it seems that when there are no children, working wives do the bulk of the shopping, and so on. But when there are children, the husband's contribution to running the home actually *declines* (in relative terms) with each child: the wife's increases by 5–10 per cent with each child (Nicholson, 1993). While there are no apparent social class differences in men's contributions to the domestic division of labour, there are cultural ones, with Swedish men doing much more than their North American counterparts (Durkin, 1995).

While childcare is still regarded as predominantly 'woman's work', mothers are increasingly likely to have a 'second career' outside the home. Whether her paid employment is full- or part-time, this is likely to be additional to her domestic duties

A survey in the UK (Montgomery, 1993) found that 82 per cent of husbands had never ironed, 73 per cent had never washed clothes, and 24 per cent had never cooked. Kremer (1998) concludes that:

> There is little evidence to suggest that domestic responsibilities have been lifted from the shoulders of women. Instead, women's dual roles (home carer and worker) persist. Indeed, even in situations where both partners are not in paid employment, or where the woman is the primary wage earner, then this pattern often still endures.

Similarly, Quiery (1998) maintains that while there have been some changes in fathers' behaviour over the last 15–20 years, they're not dramatic and the burden of child-rearing and home-making still falls on mothers. However, evidence from America suggests that a rather more significant change is taking place.

KEY STUDY 38.1 Are American men participating more in their children's activities? (Pleck, 1999)

- Pleck compared 11 studies dating from the mid-1960s to the early 1980s with 13 studies conducted between the mid-1980s and early 1990s. As shown in Figure 38.3, fathers' *engagement* with their children (as a percentage of the mothers' engagement) *increased* over that period from 34.3 to 43.5 per cent. Engagement refers to interaction with one's children, such as playing with them, reading to them, and helping them with their homework.

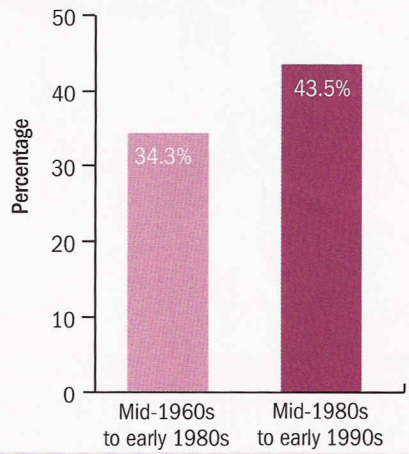


Figure 38.3 Amount of time fathers interact with their children as percentage of mothers' engagement (from Pleck, 1999)

- In that same period, fathers' *availability* also increased (again, as a percentage of the mothers') from 51.8 to 65.6 per cent (see Figure 38.4). Availability is a measure of how much time fathers spend near their children, either interacting with them or not (such as working on the computer while the children play video games).

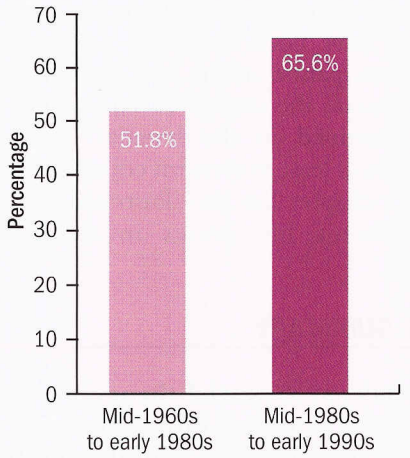

Figure 38.4 Amount of time fathers are near their children, either interacting or not, as percentage of mothers' availability (from Pleck, 1999)

Pleck (1999) concludes that although men still perform less child care than women, men's participation in family activities is increasing. However, most of the relevant data come from studies of *married* fathers, which excludes a substantial proportion of the adult male population. When these other groups are taken into account, the *opposite* picture emerges. For example, the increase in divorce rates since the 1950s has weakened many men's family ties. Most divorced fathers' contact with their children drops off rapidly after divorce. Almost half of all divorced fathers haven't seen their children in the past year, and high proportions of them don't pay child maintenance. In addition, the recent increase in the proportion of men who never marry also indicates decreasing family involvement. Most unmarried fathers – teen and adult – refuse to accept any responsibility for their children.

Thus, it seems that American family life (and probably in the UK and other western countries also) is changing in two *contradictory directions:*

1. in *two-parent families,* fathers' involvement with children and overall gender equality are increasing. In the UK, 44 per cent of new fathers took some kind of paternity leave in 2002 (compared with 9 per cent in 1999). Recent legislation should help to trigger an even bigger future rise (O'Kelly, 2004)
2. however, two-parent families have become a smaller proportion of all families, and *families headed by single mothers* have become more common. The overall effect of this is that more children don't have resident fathers (Pleck, 1999).

Pleck also challenges the popular view among social scientists (including psychologists, such as Levinson) that family is more central than work for women's identity, while the reverse is true for men. He cites evidence (from both his own and others' research) showing that family is far more central psychologically to men than work, just as it is for women. For example, fathers and mothers experience similar levels of anxiety over separation from their children during the first two years of parenthood. This suggests that 'gender-splitting' may not be such a clearly defined phenomenon as Levinson proposed. However, men are more likely to take workplace emotions home with them than are mothers, who keep these separate from their family experience.

Step-parenthood

In the early 1960s, almost 90 per cent of children spent their childhood and adolescence in homes with two biological, married parents. Now that's true of about 40 per cent of children in the USA and about 50 per cent in the UK (Hetherington & Stanley-Hagan, 1999). This is attributed to increases in divorce, out-of-wedlock childbearing, and dramatically escalating rates of cohabitation.

Although 38 per cent of white American children experience parental divorce before their 16th birthdays, the figure for African-American children is almost 74 per cent. Thus, compared with white children, more African-American children experience their parents' marital dissolutions and spend longer in single-parent households, which often include cohabiting partners and relatives.

KEY STUDY 38.2 The effects of living in a step-family (Nicholson *et al.*, 1999)

- Nicholson *et al.* examined the effects of living in a step-family during childhood and adolescence on a range of psychosocial outcomes. Data were collected for over 900 children in New Zealand as part of the Christchurch Health and Development Study. The children had all lived in step-families (for the first time) from ages 6–16, and were assessed at age 18 in terms of mental health, anti-social behaviour, substance use, restricted life opportunities, and sexual risk-taking.
- Compared with a control group (children who hadn't been exposed to step-families for the first time between 6 and 16), they were more likely to become juvenile offenders, nicotine-dependent, to abuse or become dependent on illegal substances, leave school without qualifications, engage in early sexual activity and have multiple sexual partners.
- However, when factors such as family socio-economic status, family history of instability, adversity and conflict, gender and pre-existing child-behaviour and attentional problems were controlled for, the differences became non-significant:

> Although young people exposed to living in a step-family had increased risks of poor psychosocial outcomes, much of this association appeared to be spurious and arose from confounding social, contextual and individual factors that were present prior to the formation of the step-family ... (Nicholson *et al.*, 1999)

Lesbian and gay parenting

In the context of advocating that psychologists should study homosexual relationships in their own terms (and not by comparison with heterosexual ones), Kitzinger & Coyle (1995) suggest that we might want to ask how the children of lesbian/gay couples understand and talk about their parents' relationships, and how they can develop positive views about homosexuality in a heterosexual culture. Homosexual couples have always been involved in parenting through partners' previous heterosexual relationships. The recent increase in fostering/adoption of children by gay men, and the ongoing 'lesbian baby boom', mean that many more homosexual couples are parents than used to be the case.

According to Kitzinger *et al.* (1998), research into lesbian/gay parenting was initially concerned with whether or how far the children of lesbians and (to a lesser extent) gay men could be distinguished psychologically from those of heterosexuals. On balance, this research suggested that these children were no more 'at risk' than children raised in heterosexual families.

For example, Taylor (1993) found no evidence that children reared in gay/lesbian families were more disturbed or had greater gender identity confusion than those reared in heterosexual families. Barrett & Robinson (1994) reviewed the impact of gay fathering on children. They stress the need to take into account that these children are likely to have experienced parental divorce and to show the psychological distress that often accompanies it (see Chapter 32). Although these children may be isolated, angry and in need of help sorting out their feelings about homosexuality in general, they're in little danger of being sexually abused, and adjust well to their family situations. While the relationships with their fathers may be stormy at first, they also have the potential for considerable honesty and openness.

Increasingly, psychologists are researching areas directly rooted in the concerns of lesbian/gay parents themselves, including coming out to one's children, and managing different co-parenting arrangements (such as a lesbian mother with her female lover, her ex-husband, a gay male sperm donor, or a gay male co-parent: Kitzinger *et al.*, 1998).

CONCLUSIONS

Although some of the most influential and popular explanations of personality change in early and middle adulthood have adopted *stage approaches,* critics argue that adult development doesn't occur in predictable and ordered ways. An alternative, yet *complementary,* approach is to assess the impact of *critical life events.* These include two major *normative age-graded* influences, marriage/partnering and parenthood, and one *non-normative* influence, divorce.

In the case of parenthood, the changing roles of men and women have been shown to be crucial, especially women's participation in the labour market. This means that to appreciate the impact of various life events, they must be examined in the broader context of social norms, which, at least in western countries, are constantly shifting. The chapter has also illustrated the *mutual influence* of different life events involving family and relationships.

CHAPTER SUMMARY

- In Erikson's **psychosocial theory**, the task of **young adulthood** is to achieve **intimacy** and to avoid **isolation**. The central task of **middle adulthood** is the attainment of **generativity** and avoidance of **stagnation**.
- Many people struggle with issues of identity and intimacy **at the same time**, and women tend to achieve intimacy **before** 'occupational identity', submerging their identity into that of their partners. There are also important social class, racial, and cultural differences in the timing of marriage and 'settling down'.
- Levinson *et al.* were concerned with how adulthood is actually **experienced**. Their **life-structure theory** identifies **phases/periods** that are either stable (**structure-building**) or transitional (**structure-changing**). A sequence of **eras** overlaps in the form of **cross-era transitions**.
- **Early adult transition** is a developmental bridge between adolescence and adulthood, and **entry life structure for early adulthood** is the first **structure-building** phase.
- Levinson *et al.* see **crisis** as both inevitable and necessary (**normative**). But people of all ages suffer crises ('**adolescing**'), and a growing number of people are deciding to make radical changes in their life-styles (**downshifting**), both earlier and later than 'mid-life'.
- While men have fairly unified, career-focused visions of the future, women's **dreams** are split between career and marriage/family responsibilities (**gender-splitting**).
- The **age-30 transition** generally lasts longer for women than for men, and '**settling down**' is much less clear-cut. Trying to integrate career and marriage and family responsibilities is very difficult for most women.
- The view that adult development is '**stage-like**' has been criticised on the grounds that it underestimates **individual variability**. Stage theories also imply a **discontinuity** of development.
- According to Gould, the thrust of adult development is towards **adult consciousness** and freeing ourselves of the **illusion of absolute safety**. Adult development also involves a change in the **sense of time**.

- **Marriage** and **parenting** are **normative, age-graded influences**, while **divorce** is a **non-normative influence**. These are also called **marker events** or **critical life events**.
- Couples who **cohabit** before marriage are more likely to divorce later, or be less satisfied with their marriages, than those who don't cohabit.
- **Married people** tend to live longer, and are happier, healthier and have lower rates of mental disorder than unmarried people. Men benefit most from marriage, and the potential benefits of marriage for women may be counterbalanced by gender-splitting.
- **Parenthood** has greater variability in meaning and impact than any other life transition. While pregnancy can bring couples closer together, men can feel excluded, especially after their babies are born.
- There's little evidence for **empty-nest distress**, and marital satisfaction usually increases once children have left home. The **crowded nest** is more likely to be distressing.
- The **motherhood mystique/mandate** can make women who don't bond immediately with their babies feel inadequate. But women are increasingly **postponing** having children or deciding not to have children at all.
- The motherhood mandate also implies that it's unnatural for mothers to leave their children, and that it's wrong for a mother of young children to go out to work.
- Despite evidence that domestic duties are more evenly shared in some **dual-earner families**, it's invariably the woman who's still primarily responsible for both housework and child care.
- Although **married fathers** are **engaging** more with their children, most **divorced** fathers have little contact with their children, and an increasing number of men remain unmarried and deny responsibility for their children. The overall effect is that more and more children are living without resident fathers.
- Many more **lesbian/gay couples** are parents than used to be the case. Early research examined whether the children of such parents were more 'at risk' than those raised in heterosexual families, but more recently the emphasis has shifted to issues such as co-parenting arrangements.

Links with other topics/chapters

- Normative age-graded influences and non-normative influences include many of the *life events* listed in Holmes and Rahe's *Social Readjustment Rating Scale* measure of *stress* (Chapter 12).
- According to Gilligan, Erikson's theory is *androcentric* (male-centred), but is still meant to apply equally to males and females (Chapter 47).
- Levinson *et al.*'s claim that separation from our parents is never complete is consistent with the evidence which shows that securely attached *adolescents* find it *easier* to achieve independence (Chapter 37). They use 'attachment' differently from *attachment theorists,* because they talk about attachment to 'the world', rather than to *attachment figures* (Chapter 32).
- The debate regarding the validity of seeing adult development in terms of distinct stages mirrors that in relation to children's *cognitive development* (Chapter 34).
- Gould's theory is really an extension of the Freudian idea of *separation anxiety* (Chapter 32).
- What's fast becoming *the norm* as far as the appropriate age to marry and have children would have been considered *deviant* in previous generations (and vice-versa). This illustrates the more general issue as to how *definitions of normality* can and do change over time (Chapter 43).
- Marriage cannot be the same type of transition for everyone. In some cultures, for example, people have little choice as to who their partners will be (as in *arranged marriages:* Chapter 28).
- Much of the research into *interpersonal relationships* has focused on marriage and other forms of long-term partnering, including the reasons for the *breakdown* of relationships (e.g. divorce) (Chapter 28).
- The psychological effects of divorce have been investigated mainly from the perspective of *the child*. If, as research strongly suggests, the most damaging factor is *marital conflict,* then relief from this may be beneficial for both children and parents (Chapter 32).
- The effects of being raised by gay or lesbian couples have been studied in relation to *gender identity* and *sexual orientation* (Chapter 36), and the influence of *early experience* on later development (Chapter 32).

OLD AGE

INTRODUCTION AND OVERVIEW

While 'growing up' is normally seen as desirable, 'growing old' usually has far more negative connotations. The negative view of ageing is based on the *decrement model*, which sees ageing as a process of decay or decline in physical and mental health, intellectual abilities and social relationships.

An alternative to the decrement model is the *personal growth model*, which stresses the potential advantages of late adulthood (or 'old age'), such as increased leisure time, reduced responsibilities, and the ability to concentrate only on matters of high priority (Kalish, 1982). This much more positive view is how ageing has been studied within the *lifespan approach*.

In this chapter we consider some of the theories and research concerned with *adjustment to late adulthood*. It begins by looking at what's meant by the term 'old', which turns out to be more complex than it might seem. *Stereotyped beliefs* about what elderly people are like are an inherent part of prejudiced attitudes towards them. Research into some of the cognitive and social changes that occur in late adulthood bring these stereotypes and prejudice into sharp focus. The chapter also discusses the impact of two major life events, *retirement* (a *normative, age-graded influence*, often taken to mark the 'official' start of old age) and *bereavement* (a *non-normative influence*, although death of one's spouse becomes increasingly likely as we attain late adulthood).

THE MEANING OF 'OLD'

ASK YOURSELF...
- How old is old?
- Is 'old' simply a matter of chronological age?

People today are living longer and retaining their health better than any previous generation (Baltes & Baltes, 1993). The proportion of older people in the British population has increased dramatically in recent years. In 1961, 2 per cent of the population (one million people) were aged 80 or over. By 1991, this figure had risen to 4 per cent (two million people). The number of centenarians has risen from 271 (in 1951), to 1185 (1971), to 4400 (1991). In 1997, the number stood at 8000 with projections of 12,000 (2001) and 30,000 (2030) (McCrystal, 1997). Figures for the USA show that the number of centenarians doubled between 1990 and 2000, and may increase more than eleven-fold by 2050 (Brown, 2000).

The oldest person who ever lived: Jeanne Calment died in 1997 at the age of 122

Because of this *demographic imperative* (Swensen, 1983), developmental psychologists have become increasingly interested in our later years. But what do we mean by 'old'? Kastenbaum's (1979) '*The ages of me*' questionnaire assesses how people see themselves at the present moment in relation to their ages (see Box 39.1).

ASK YOURSELF...
- How old are you according to Kastenbaum's questionnaire?

Box 39.1 Kastenbaum's 'The ages of me' questionnaire

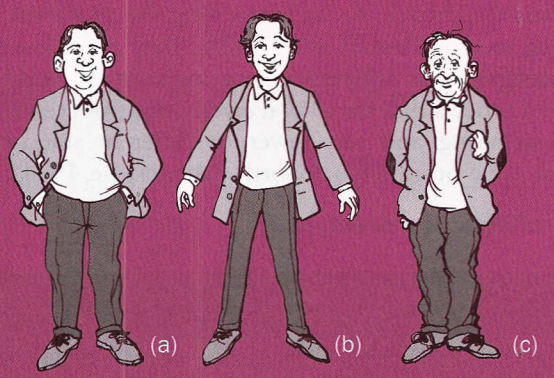

Figure 39.1 While (c) might depict someone's chronological age, (a) might correspond to his biological age and (b) might represent his subjective age

- My **chronological age** is my actual or official age, dated from my time of birth. My chronological age is ...
- My **biological age** refers to the state of my face and body. In other people's eyes, I look as though I am about ... years of age. In my own eyes, I look like someone of about ... years of age.
- My **subjective age** is indicated by how I feel. Deep down inside, I really feel like a person of about ... years of age.
- My **functional age**, which is closely related to my **social age**, refers to the kind of life I lead, what I am able to do, the status I believe I have, whether I work, have dependent children and live in my own home. My thoughts and interests are like those of a person of about ... years of age, and my position in society is like that of a person of about ... years of age.

(Adapted from Kastenbaum, 1979)

Few people, irrespective of their chronological age, describe themselves *consistently* (that is, they tend to give *different* responses to the different questionnaire items). For example, people over 20 (including those in their 70s and 80s) usually describe themselves as feeling younger than their chronological age. We also generally consider ourselves to be *too* old.

It seems, then, that knowing a person's chronological age tells us little about the sort of life that person leads or what s/he is like. However, one of the dangerous aspects of ageism is that chronological age is assumed to be an accurate indicator of all the other ages. According to Comfort (1977), ageism is:

> ... the notion that people cease to be people, cease to be the same people or become people of a distinct and inferior kind by virtue of having lived a specified number of years ... Like racism, which it resembles, it is based on fear.

Similarly, Bromley (1977) argues that most people react adversely to the elderly because they seem to deviate from our concept of 'normal' human beings. As part of the 'welfarist approach' to understanding the problems of an ageing society (Fennell *et al.*, 1988), 'they' (i.e. the elderly) are designated as different, occupying another world from 'us' – a process that for all perceived minorities tends to be dehumanising and sets lower or different standards of social value or individual worth (Manthorpe, 1994).

The effects of stereotyping

Box 39.2 Can stereotypes make you ill?

- In April 2000, the charity Age Concern highlighted the plight of Jill Baker, a cancer patient in her sixties. She was shocked to discover that, despite still being in a generally good state of health, a junior doctor she'd never met had put 'not for resuscitation' on her records.
- According to Ebrahim (in Payne, 2000): Medical students still rejoice in their stereotypes of '*geriatric crumbly*' and '*GOMER*' (get out of my emergency room) patients.
- Ebrahim cites US evidence showing that 'do not resuscitate' orders are commonly used for people with HIV, blacks, alcohol misusers, and non-English speakers, suggesting that doctors have stereotypes of who isn't worth saving.
- In the UK, one in 20 people aged over 65 had been refused treatment by the NHS, with one in ten over-fifties believing they were treated differently (i.e. worse) because of their age (based on an Age Concern survey).

Adler (2000) cites American research by Levy and her colleagues showing that stereotypes can affect how the elderly think about themselves in ways that can be detrimental to their mental and physical health. In one study, elderly participants spent a few minutes concentrating on a computer-based reaction-time test. Age-related words were subliminally presented on the screen (too quickly to be consciously registered), and were either negative (e.g. 'senile, 'forgetful', diseased'), or positive (e.g. 'wise', 'astute', 'accomplished').

The participants were subsequently asked if they'd request an expensive but potentially life-saving medical treatment, without which they'd die within a month. Most of those who'd 'seen' the positive words (evoking a positive stereotype) chose the life-saving treatment, but most of those who were exposed to negative words declined.

In another study, participants were challenged with a series of maths problems following ten minutes' exposure to positive or negative words. Those exposed to the latter showed signs of stress – heart rate, blood pressure, and skin conductance all increased and stayed high for over 30 minutes. In contrast, those exposed to positive words sailed through the challenge stress-free.

Since many studies have linked chronic stress to disease (see Chapter 12), Levy suspects that repeated triggering of negative stereotypes over a period of several years may be making elderly people ill (Adler, 2000). (Levy's research is discussed further in Key Study 39.1, page 671.)

ASK YOURSELF...

- If you're being honest, do you stereotype elderly people ('the elderly')?
- If so, what characteristics do you attribute to them?

Stereotypes of the elderly are more deeply entrenched than (mis)conceptions of gender differences. It's therefore not surprising that people are overwhelmingly unenthusiastic about becoming 'old' (Stuart-Hamilton, 1997). According to Jones (1993), everyone over retirement age is seen as forming a strange homogeneous mass, with limited abilities, few needs and few rights:

> What other section of the population that spans more than 30 years in biological time is grouped together in such an illogical manner? ... As a consequence, older people suffer a great deal ... As for experience and wisdom, these qualities are no longer valued in this fast-moving high-technology world. They are devalued by the community, as well as by their owners ... (Jones, 1993)

Box 39.3 A decade-by-decade description of 'the elderly'

The young old (60–69): This period marks a major transition. Most adults must adapt to new role structures in an effort to cope with the losses and gains of the decade. Income is reduced due to retirement. Friends and colleagues start to disappear. Although physical strength wanes somewhat, a great many young old have surplus energy and seek out new and different activities.

The middle-aged old (70–79): This is often marked by loss or illness. Friends and family may die. The middle-aged old must also cope with reduced participation in formal organisations, which can produce restlessness and irritability.

Their own health problems become more severe. The major developmental task is to maintain the personality reintegration achieved in the previous decade.

The old old (80–89): The old old show increased difficulty in adapting to and interacting with their surroundings. They need help in maintaining social and cultural contacts.

The very old old (90–99): Although health problems become more acute, the very old old can successfully alter their activities to make the most of what they have. The major advantage of old age is freedom from responsibilities. If previous crises have been resolved satisfactorily, this decade may be joyful, serene and fulfilling.

(Based on Burnside *et al.*, 1979, and Craig, 1992)

As Box 39.3 suggests, the aged aren't one cohesive group (Craig, 1992). Rather, they're a collection of subgroups, each with its unique problems and capabilities, but all sharing to some degree the age-related difficulties of reduced income, failing health, and the loss of loved ones. For Craig, however:

> Having a problem is not the same as being a problem, and the all-too-popular view of those over age 65 as needy, non-productive, and unhappy needs revision.

Similarly, Dietch (1995) has commented that:

> Life's final stage is surrounded by more myths, stereotypes and misinformation than any other developmental phase.

COGNITIVE CHANGES IN OLD AGE

Consistent with the *decrement model* (see *Introduction and overview*), it's commonly believed that old age is associated with a decrease in cognitive abilities. Until recently, it was thought that intellectual capacity peaked in the late teens or early twenties, levelled off, and then began to decline fairly steadily during middle age and more rapidly in old age.

The evidence on which this claim was based came from *cross-sectional studies* (studying different age groups at the same time).

ASK YOURSELF...

- Why can't we generalise from cross-sectional studies?

However, we cannot draw firm conclusions from such studies, because the age groups compared represent different generations with different experiences (the *cohort effect*). Unless we know how 60-year-olds, say, performed when they were 40 and 20, it's impossible to say whether or not intelligence declines with age.

An alternative methodology is the *longitudinal study*, in which the same people are tested and retested at various times during their lives. Several such studies have produced data contradicting the results of cross-sectional studies, indicating that at least some people retain their intellect well into middle age and beyond (Holahan & Sears, 1995). However, the evidence suggests that there are some age-related changes in different kinds of intelligence and aspects of memory.

Changes in intelligence

Although psychologists have always disagreed about the definition of intelligence, there's general acceptance that it's *multi-dimensional* (composed of several different abilities). An important – and very relevant – distinction is that between crystallised and fluid intelligence.

- *Crystallised intelligence* results from accumulated knowledge, including a knowledge of how to reason, language skills, and an understanding of technology. This type of intelligence is linked to education, experience and cultural background, and is measured by tests of general information.
- *Fluid intelligence* is the ability to solve novel and unusual problems (those not experienced before). It allows us to perceive and draw inferences about relationships among patterns of stimuli and to conceptualise abstract information, which aids problem-solving. Fluid intelligence is measured by tests using novel and unusual problems not based on specific knowledge or particular previous learning.

Crystallised intelligence *increases* with age, and people tend to continue improving their performance until near the end of their lives (Horn, 1982). Using the *cross-longitudinal method* (in which *different* age groups are *retested* over a long period of time), Schaie & Hertzog (1983) reported that fluid intelligence *declines* for all age groups over time, peaking between 20 and 30.

Explaining changes in intelligence

ASK YOURSELF...

- Try to account for these findings. (It may help to think both of what happens to people as they get older, as well as the nature of intelligence tests themselves – see Chapter 41.)

Intelligence tests are typically heavily loaded with *fluid* intelligence questions at the expense of crystallised, and they are also usually *timed*. This implies that tests of general intelligence are biased against older people (see below). But tests of crystallised intelligence are, arguably, biased *in favour* of older people (there's usually *no* time limit). However, removing the time limit from tests of fluid intelligence doesn't remove the age difference – but it does reduce it. So, the preservation of crystallised intelligence in later life is, in part, illusory (Stuart-Hamilton, 2000).

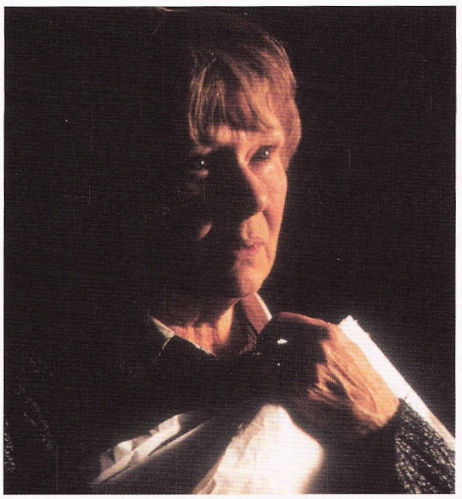
Physiological changes (such as cardiovascular and metabolic dysfunction) can have serious effects on physiological processes in the brain; in turn, these can lower intellectual performance. For example, *response times* (RTs) are a good indicator of how efficiently the nervous system operates. Not only do we get slower as we get older, but this slowing is strongly correlated with IQ test scores: the slower the RTs, the lower the test score (the *general slowing hypothesis:* Stuart-Hamilton, 2003).

According to Storandt (1976), writing speed accounted for half the difference between old and young people on certain intelligence tests. The prime cause of the decline in intelligence in elderly people is a slowing of nervous system processes (Stuart-Hamilton, 2003). Some argue that an even better indication of change is the state of the *sensory systems* (as measured by vision and hearing). A composite index composed of measures of sensory efficiency correlates impressively with IQ test scores (Baltes & Lindenberger, 1997). Alternative measures of intellectual activity (such as problem-solving or memory: see below) are highly correlated with IQ (Rabbitt, 1993).

Box 39.4 Compensating for slowing down

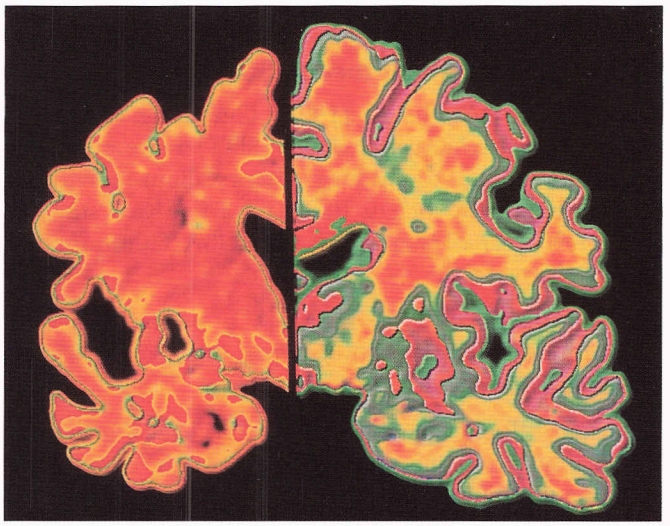
- A proportion of older people never lose their youthful level of performance. For example, Rabbitt (1980) estimated that 15 per cent maintain their intellectual performance throughout life. This may be partly genetic, partly due to the level and type of their daily intellectual activity. Regular practice at intellectual skills means they're maintained at or near to a youthful level ('use it or lose it': Stuart-Hamilton, 2000).
- A longitudinal study by Schooler & Mulatu (2001) found that people who engage in intellectually demanding work or hobbies also tend to have 'better preserved' intellectual abilities. Such individuals have a lower incidence of dementia, or their symptoms may be less pronounced (Snowdon *et al.*, 2000: see text below).
- Older chess and bridge players perform at the same level as younger opponents (Charness, 1979, 1981). Although they had poorer memories, they could draw on a greater store of strategies and tactics. They *compensated* for the lowering of basic skills by calling on their higher level of experience.
- Such people are reversing the normal trend, which is that we're less often challenged to use our fluid abilities in old age (Cavanaugh, 1995).
- The tendency to continue adding to our knowledge as we grow older could account for the constancy of crystallised intelligence. Alternatively, regular use of our crystallised abilities may help to maintain them (Denney & Palmer, 1981).

Greater experience can compensate for reduction in basic skills



Changes in memory

Some aspects of memory appear to decline with age, possibly because we become less effective at processing information (which may underlie cognitive changes in general: Stuart-Hamilton, 1994). On *recall* tests, older adults generally perform more poorly than younger adults. But the reverse is sometimes true, as shown by Maylor's (1994) study of the performance of older contestants on *Mastermind*. On *recognition* tests, the differences between younger and older people are less apparent and may even disappear. As far as everyday memory is concerned, the evidence indicates that the elderly do have trouble recalling events from their youth and early lives (Miller & Morris, 1993).



Alzheimer's disease

Significant memory deficits are one feature of dementia, the most common form of which is *Alzheimer's disease* (AD). AD accounts for about half of all cases of dementia, but only 5–15 per cent of over 65s and 20–40 per cent of over 80s are affected (Voss, 2002). Even very late in life cortical neurons seem capable of responding to enriched conditions by forming new functional connections with other neurons. This is supported by the finding that those who keep mentally active are those who maintain their cognitive abilities (Rogers *et al.*, 1990: see above).

AD is one of the most debilitating and dreaded of the common diseases of ageing. It's estimated that over one million people in the UK will be affected by it by 2010. It used to be described more generally as 'senile dementia', but is now referred to as 'senile dementia of the Alzheimer's type'. People at the height of their intellectual powers can be struck down with it. Patients experience a frightening loss of sense of their own identity and access to their store of personal memories. Their brains shrink, and the neurons themselves change appearance (they develop 'tangles and plaques') (Rose, 2003).

Judi Dench as Iris Murdoch, the gifted novelist and academic, in *Iris* (2001). She died from Alzheimer's disease

A CT scan of the brain of an Alzheimer's patient (left) and of a normal person (right)

Disease process or part of normal ageing?

Some researchers claim that Alzheimer's disease is an *accelerated form* of normal changes in the ageing brain, so that we'd all get the disease if we lived long enough. The opposing view is that cognitive decline isn't an inevitable part of ageing, but rather it reflects a *disease process* which is more likely to affect us as we get older (Smith, 1998). Work by the Oxford Project to Investigate Memory and Ageing (OPTIMA) has used X-ray computerised tomography (CT: see Chapter 4) to examine the *medial temporal lobe* (again see Chapter 4). While this tiny area comprises only 2 per cent of the volume of the whole cerebral cortex, it includes the *hippocampus,* a structure known to be crucial for memory (see Chapter 17). Also, the neurons of the medial temporal lobe connect with almost all other parts of the cortex, so any damage to this part of the brain is likely to have consequences for the functioning of the rest of the cortex.

X-ray CT images show that the medial temporal lobe is markedly smaller in people with dementia who eventually die of Alzheimer's disease than in age-matched controls without cognitive deficit. Repeated CT scans over periods of several years have found that shrinkage is slow in control participants (about 1–1.5 per cent per year), compared with an alarming rate of some 15 per cent per year in Alzheimer's patients (Smith, 1998).

These and other supportive data led the OPTIMA researchers to conclude that Alzheimer's disease is distinct from normal ageing, and that it cannot be simply an acceleration of normal ageing. Although cognitive decline does appear to increase with age for the population as a whole, if we rigorously exclude those with pathological changes (such as early Alzheimer's), then a majority may not show any significant decline. According to Smith (1998):

> We must abandon the fatalistic view that mental decline is an inevitable accompaniment of ageing.

Consistent with this conclusion is the belief that negative cultural stereotypes of ageing actually cause memory decline in the elderly.

KEY STUDY 39.1 The influence of stereotypes on memory (Levy & Langer, 1994)

- Levy and Langer investigated the memory capabilities of hearing Americans, members of the American deaf community, and people from mainland China.
- It was assumed that members of the deaf community were less likely to have been exposed to negative cultural stereotypes. People from mainland China were chosen because of the high esteem in which Chinese society holds its aged members.
- The older American deaf participants and the Chinese participants performed much better on memory tasks than the older American hearing participants.
- Also, younger hearing Americans held less positive views of ageing than any of the other groups. Amongst the older participants, attitudes towards ageing and memory performance were positively correlated.
- Levy and Langer believe that negative stereotypes about ageing may become *self-fulfilling prophecies,* so that low expectations mean that people are less likely to engage in activities that will help them maintain their memory abilities.
- The *subliminal* (below conscious awareness) presentation of negative self-stereotypes (e.g. 'Because of my age I am forgetful') tended to worsen memory performance, while positive self-stereotypes (e.g. 'Because of my age I have acquired wisdom') tended to improve it (Levy, 1996). Levy found no such effect with young participants, for whom stereotypes of ageing are obviously less salient (see text above, page 668).

Social disengagement theory (SDT)

According to Manthorpe (1994), Cumming & Henry's (1961) *social disengagement theory* (SDT) represented the first major attempt to produce a theory about individuals' relationships with society. Based on a five-year study of 275 50–90-year-olds in Kansas City, USA, Cumming and Henry claimed that:

> Many of the relationships between a person and other members of society are severed and those remaining are altered in quality.

This social disengagement involves the *mutual withdrawal* of society from the individual (through compulsory retirement, children growing up and leaving home, the death of a spouse, and so on) and of the individual from society (Cumming, 1975). As people grow older, they become more solitary, retreat into the inner world of their memories, become emotionally quiescent, and engage in pensive self-reflection.

Cumming sees disengagement as having three components:

1. *shrinkage of life space* refers to the tendency to interact with fewer other people as we grow older, and to occupy fewer roles
2. *increased individuality* means that in the roles that remain, older people are much less governed by strict rules and expectations
3. *acceptance* (even embrace) *of these changes,* so that withdrawal is a voluntary, natural, and inevitable process, and represents the most appropriate and successful way of growing old.

As far as society is concerned, the individual's withdrawal is part of an inevitable move towards death – the ultimate disengagement (Manthorpe, 1994). By replacing older individuals with younger people, society renews itself and the elderly are free to die (Bromley, 1988).

An evaluation of social disengagement theory

- Bee (1994) sees the first two components as difficult to dispute. However, the third is more controversial because of its view of disengagement as a natural, voluntary, and inevitable process, rather than an imposed one.
- Bromley (1988) argues that such a view of ageing has detrimental *practical* consequences for the elderly, such as encouraging a policy of segregation, even indifference, and the very destructive belief that old age has no value. For Bromley, an even more serious criticism concerns whether everyone actually does disengage.

KEY STUDY 39.2 Do the elderly disengage? (Havighurst *et al.*, 1968)

- Havighurst *et al.* followed up about half the sample originally studied by Cumming & Henry (1961).
- Although increasing age was accompanied by increasing disengagement, at least some remained active and engaged, and they tended to be the happiest. The fact that those who disengage the least are the happiest, have the highest morale and live the longest, contradicts SDT's view that withdrawal from mainstream society is a natural and inherent part of the ageing process (Bee, 1994).
- While some people may choose to lead socially isolated lives and find contentment in them, such disengagement doesn't appear to be necessary for overall mental health in old age.
- Havighurst *et al.* also identified several different *personality types*. These included:
  - *reorganisers*, who were involved in a wide range of activities and reorganised their lives to compensate for lost activities, and
  - the *disengaged*, who voluntarily moved away from role commitments.
- Consistent with SDT, the latter reported low levels of activity but high 'life satisfaction'. However, the disposition to disengage is a *personality dimension* as well as a characteristic of ageing (Bromley, 1988).

- SDT focuses on *quantitative* changes, such as the reduced number of relationships and roles in old age. But for Carstensen (1996), it's the *qualitative* changes that are crucial:

> Although age is associated with many losses, including loss of power, social partners, physical health, cognitive efficiency, and, eventually, life itself – and although this list of losses encompasses the very things that younger people typically equate with happiness – research suggests that older people are at least as satisfied with their lives as their younger counterparts.

The importance of friendships

Although many of these losses are beyond the older person's control (Rosnow, 1985), such as retirement (see below), *friendships* are voluntary, non-institutionalised, and relatively enduring relationships which offer comfort and stability. Informal support from friends (and other primary relationships) also reduces dependency on social security agencies, the helping professions and other formal organisations (Duck, 1991; Rainey, 1998). It's the choice element that differentiates friendships from other types of relationships (Baltes & Baltes, 1986), providing older people with control over at least one life domain (Rainey, 1998).

Maintaining close relationships with others is often a significant factor in determining whether older people feel a sense of belonging to the social system. This may become more important with age, because society withdraws from

older adults both *behaviourally* (compulsory retirement) and *attitudinally* (attributing diminishing powers, abilities and qualities to the elderly). Both relatives and friends are crucial for determining how life is experienced by the elderly. Overall, individual adaptation to old age on all levels has been shown to be highly dependent on personal tolerance of stress and life events, and on the availability of informal social support networks (Duck, 1991). These findings regarding the role of friendships and other relationships are consistent with *socioemotional selectivity theory* (see pages 674-675).

Activity (or re-engagement) theory (AT)

The major alternative to SDT is *activity* (or *re-engagement*) *theory* (AT) (Havighurst, 1964; Maddox, 1964). Except for inevitable biological and health changes, older people are essentially the same as middle-aged people, with the same psychological and social needs. Decreased social interaction in old age is the result of the withdrawal of an inherently ageist society from the ageing person, and happens against the wishes of most elderly people. The withdrawal *isn't* mutual.

Optimal ageing involves staying active and managing to resist the 'shrinkage' of the social world. This can be achieved by maintaining the activities of middle age for as long as possible, and then finding substitutes for work or retirement (such as leisure or hobbies) and for spouses and friends upon their death (such as grandchildren). It's important for older adults to maintain their role counts, to ensure they always have several different roles to play.

An evaluation of activity theory

ASK YOURSELF...

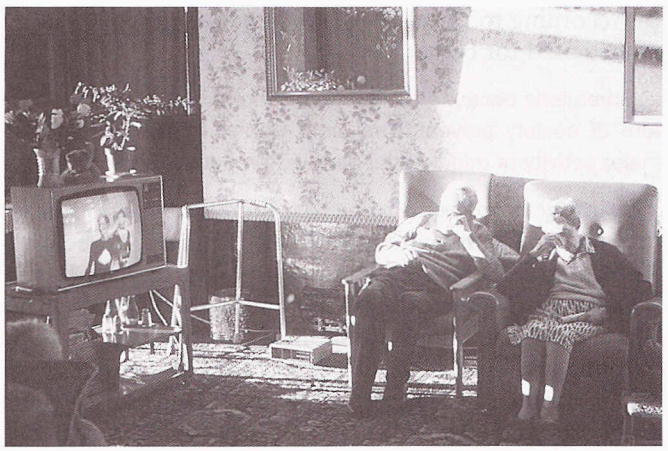
Can you think of any objections to activity theory?

- Is it realistic?
- Does it repeat any of the mistakes of SDT?

Activity theory personified

- According to Bond *et al.* (1993), activity theory can be criticised for being:

> ... unrealistic because the economic, political and social structure of society prevents the older worker from maintaining a major activity of middle age, namely, 'productive' employment.



The implication seems to be that there really is no substitute for paid employment (at least for men: see below). According to Dex & Phillipson (1986), society appears to measure people's worth by their ability to undertake paid labour, and the more autonomous people are in their working practices, the more respect they seem to deserve. When someone retires, they not only lose their autonomy and right to work for money, but they also lose their *identity:* they cease to be a participant in society and their status is reduced to 'pensioner/senior citizen' or simply 'old person'.

- As noted in Key Study 39.2, some elderly people seem satisfied with disengagement, suggesting that AT alone cannot explain successful ageing. Nevertheless, activity or re-engagement prevents the consequences of disengagement from going too far in the direction of isolation, apathy, and inaction.
- Just as disengagement may be involuntary (as in the case of poor health), so we may face involuntarily high levels of activity (as in looking after grandchildren). Both disengagement and activity may, therefore, be equally maladaptive. SDT may actually *under*estimate, and AT *over*estimate, the degree of control people have over the 'reconstruction' of their lives.
- Additionally, both theories see ageing as essentially the same for everyone. They both refer to a legitimate process through which some people come to terms with the many changes that accompany ageing (they represent *options:* Hayslip & Panek, 1989). However, people will select styles of ageing best suited to their personalities and past experiences or lifestyles, and there's no single 'best way' to age (Neugarten & Neugarten, 1987). For Turner & Helms (1989), personality is the key factor, and neither theory can adequately explain successful ageing.
- Increasingly, theorists are emphasising the *continuity* between earlier and later phases of life. Satisfaction, morale, and adaptations in later life seem to be closely related to a person's life-long personality style and response to stress and change. According to Reedy (1983):

> In this sense, the past is the prologue to the future. While the personality changes somewhat in response to various life events and changes, it generally remains stable throughout all of adult life.

Social exchange theory (SET)

According to Dyson (1980), both SDT and AT fail to take sufficient account of the physical, social, and economic

The elderly couple above seem to fit the stereotype of the withdrawn, isolated, 'disengaged' person, while the couple below illustrate an alternative, but less common, stereotype, of the person who remains as active in old age as when s/he was middle-aged

factors which might limit people's choices about how they age. Age robs people of the capacity to engage in the reciprocal give-and-take that is the hallmark of social relationships, and thus weakens their attachment to others. In addition, Dowd (1975) argues that:

> Unlike the aged in traditional societies, older people in industrialised societies have precious few power resources to exchange in daily social interaction.

This inequality of power results in dependence on others and compliance with others' wishes. But for both Dyson and Dowd, there's a more positive aspect to this loss of power. Adjusting to old age in general, and retirement in particular, involves a sort of *contract* between the individual and society. The elderly give up their roles as economically active members of society, but in *exchange* they receive increased leisure time, take on fewer responsibilities, and so on. Although the contract is largely unwritten and not enforceable, most people will probably conform to the expectations about being old which are built into social institutions and stereotypes (see Key Study 39.1).

Socioemotional selectivity theory (SST)

According to *socioemotional selectivity theory* (SST) (Carstensen, 1992, 1993; Carstensen & Turk-Charles, 1994), social contact is motivated by various goals, including basic survival, information-seeking, development of self-concept, and the regulation of emotion. While these all operate throughout life, the importance of specific goals varies, depending on one's place in the life cycle. For example, when *emotional regulation* is the major goal, people are highly selective in their choice of social partners, preferring familiar others. This selectivity is at its peak in infancy (see Chapter 32) and old age: the elderly turn increasingly to friends and adult children for emotional support (see above).

According to SST, a major factor contributing to these changes in social motives is *construal of the future,* which is indicated by chronological age. When the future is perceived as largely open-ended, long-term goals assume great significance. But when the future is perceived as limited (see Gould's theory, page 656), attention shifts to the *present*. Immediate needs, such as emotional states, become more salient. So, contrary to SDT (which sees reduced social contact as being caused by emotional states becoming diluted and dampened down), SST predicts that emotional concerns will become *more* important in old age.

An evaluation of SST

- If SST is correct, it would follow that when younger people hold expectations about the future which are similar to those of the elderly, they should make the same kinds of social choices as those typically made by older people.

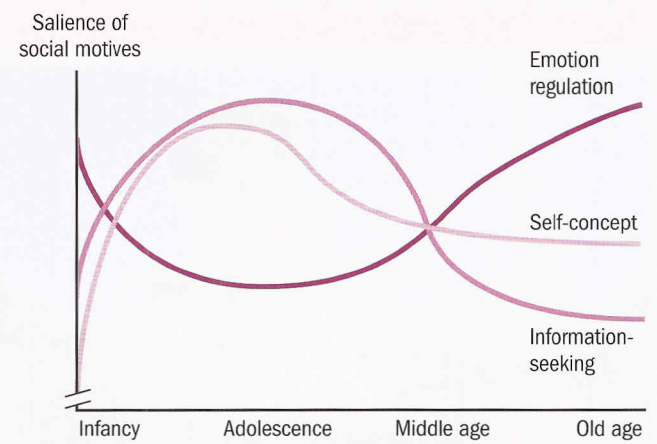


Figure 39.2 Idealised illustration of the lifespan trajectory (from Carstensen, Socioemotional selectivity: A life-span developmental account of social behaviour. In M.R. Merrens & G.C. Brannigan (eds) *The Developmental Psychologists: Research Adventures across the Life-Span*. Copyright 1996, reproduced with permission of the McGraw-Hill Companies.)

KEY STUDY 39.3 How a limited future can influence current concerns (Carstensen, 1996)

- Carstensen describes a study involving a group of healthy gay men, a group of HIV-positive, asymptomatic gay men, and a group of HIV-positive, symptomatic gay men. A group of young, middle-aged and old men representing the general population served as a control group.
- The social preferences of the healthy gay men were similar to those of the young men from the control group. Those of the asymptomatic group mimicked those of the middle-aged controls, while those of the symptomatic group were strikingly similar to those of the oldest control participants. In other words:

The closer the men were to the end of their lives, the greater weight they placed on affective qualities of prospective social partners ... changes in social preferences appear to be altered in much the same way when futures are limited by age as when futures are limited by disease ... (Carstensen, 1996)

- According to Carstensen (1996), the findings relevant to SST taken together paint quite an optimistic picture. Age-related reduction in social contact appears to be highly selective (rather than reflecting a reduced capacity), such that interaction is limited to those people who are most familiar and can provide the greatest emotional security and comfort. This is an excellent strategy when time and social energy need to be invested wisely.

Psychosocial theory

Another alternative to SDT and AT is Erikson's *psychosocial theory* (see Chapter 38). A more valid and useful way of looking at what all elderly people have in common might be to examine the importance of old age as a stage of development, albeit the last (which is where its importance lies).

Erikson's theory suggests that in old age, there's a conflict between *ego-integrity* (the positive force) and *despair* (the negative force). As with the other psychosocial stages, we cannot avoid the conflict altogether, which occurs as a result of biological, psychological, and social forces. The task is to end this stage, and hence life, with greater ego-integrity than despair, and this requires us to take stock of our life, reflect on it, and assess how worthwhile and fulfilling it has been.

The characteristics of ego-integrity

- We believe that life does have a purpose and makes sense.
- We accept that, within the context of our lives as a whole, what happened was somehow inevitable and could only have happened when and how it did.
- We believe that all life's experiences offer something of value, and that we can learn from everything that happens to us. Looking back, we can see how we have grown psychologically as a result of life's ups and downs, triumphs and failures, calms and crises.
- We see our parents in a new light and understand them better, because we've lived through our own adulthood and have probably raised children of our own.
- We realise that we share with all other human beings, past, present and future, the inevitable cycle of birth and death. Whatever the historical, cultural and other differences, we all have this much in common. In the light of this, death 'loses its sting'.

Fear of death is the most conspicuous symptom of despair. In despair, we express the belief that it's too late to undo the past and turn the clock back in order to right wrongs or do what hasn't been done. Life isn't a 'rehearsal'; this is the only chance we get.

RETIREMENT

Retirement has figured prominently in the discussion above of theories of social adjustment in old age. As a *normative, age-graded influence,* it's an inevitable and anticipated loss of work, which many people experience without undue psychological upheaval (Raphael, 1984). However, it may be unacceptable to those who, for example, see themselves as 'too young' to stop work.

ASK YOURSELF...

- What do you imagine some of the major benefits and negative aspects of retirement might be?

One consequence of retirement is the loss of everyday, ritualised patterns of activity, which contribute to the very fabric of our lives. While the early weeks of not working may be celebrated, emptiness may be experienced for a time following retirement. As the months pass, frustration and a sense of 'uselessness' can set in, and this may produce an angry and irritable response to the world.

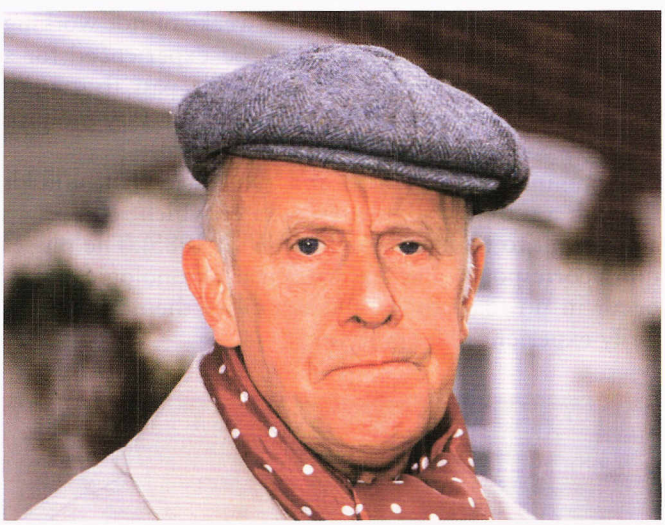
Retirement is a *process* and *social role* that unfolds through a series of six phases, each of which requires an adjustment to be made (Atchley, 1982, 1985). The phases don't correspond with any particular chronological ages, occur in no fixed order, and not all of them are necessarily experienced by everyone.

Box 39.5 The six phases in the process of retirement

Pre-retirement phase: (i) In the *remote* subphase, retirement is seen as being in a reasonably distant future; (ii) the *near* subphase may be initiated by the retirement of older friends and colleagues, and there may be much anxiety about lifestyle changes, especially financial ones.

Honeymoon phase (immediate post-retirement): This typically involves euphoria, partly due to newfound freedom, and is often a busy period.

Disenchantment phase: This involves a slowing down after the honeymoon phase, with feelings of being let down and even depression. The degree of disenchantment is related to declining health and finances. Eagerly anticipated postretirement activities (e.g. travel) may lose their original appeal. Disenchantment may be produced by unrealistic pre-retirement fantasies, or inadequate preparation for retirement.



Reorientation phase: This is a time to develop a more realistic view of life alternatives, and may involve exploring new avenues of involvement, sometimes with the help of community groups (e.g. special voluntary or paid jobs for the retired). This helps to decrease feelings of role loss and is a means of achieving *self-actualisation* (see Chapter 9).

Stability phase: This involves the establishment of criteria for making choices, allowing people to deal with life in a fairly comfortable and orderly way. They know what's expected of them, what their strengths and weaknesses are, allowing mastery of the retirement role.

Termination phase: Illness and disability usually make housework and self-care difficult or impossible, leading to the assumption of a sick or disabled (as opposed to retired) role.

(Based on Atchley, 1982, and Atchley & Robinson, 1982)

People who retire *voluntarily* seem to have very little or no difficulty in adjusting. But those who retire because they've reached a compulsory age tend to be dissatisfied at first, although they eventually adapt. The least satisfied are those whose health is poor when they retire (which may have caused their retirement), although health often improves following retirement.

Victor Meldrew (star of BBC TV's *One Foot in the Grave*) seems to personify the sense of frustration and uselessness that often sets in, especially for men, after the 'honeymoon period' of retirement

Bromley (1988) believes that it's the *transition* between employment and retirement that causes adjustment problems. Those who are most satisfied in retirement tend to be scientists, writers and other academics, who simply carry on working with little loss of continuity from very satisfying jobs. Those who discover satisfying leisure activities, with at least some of the characteristics of work, also adjust well. Conversely, some people decide to take *early retirement* (for reasons other than ill-health). This means that retirement isn't necessarily a sudden and enforced dislocation of a working life, inevitably causing feelings of rejection and producing psychological problems.

Retirement and gender

ASK YOURSELF...

- What particular problems would you expect retiring women to experience?

As we saw in Chapter 38, women are increasingly entering the labour market and remaining in it, and so more and more women are having to adjust to their own retirement. At the same time, 'gender-splitting' will mean that home and family still occupy a major part of a working woman's time, and retirement will involve less of a lifestyle change than it will for her husband.

According to Rainey (1998), the increase in numbers of working women aged 45–64 is particularly significant. They're the very age-group that, traditionally, contributes the most time to voluntary organisations and provides informal support for the elderly. There's no evidence that these women are abandoning their caring roles. In fact, these 'women in the middle' appear to be assuming multiple roles: caring for their own families (which includes helping their husbands adjust to retirement and, increasingly, still caring for grown-up children: see Chapter 38), for aged parents, possibly parents-in-law, as well as working. They're caught in the 'caring trap' (Rainey, 1998).

Retirement and unemployment

While retirement is an *anticipated* loss of work, unemployment is sudden and generally unanticipated. According to Campbell (1981), retirement is also an accepted and 'honourable' social status (it's 'achieved'), whereas unemployment isn't. Moreover, retirement is seen as a proper reward for a lifetime of hard work, while for many people unemployment implies failure, being unwanted (or incompetent), and a 'scrounger' who's 'living off the state'. There's a stigma attached to unemployment which can make it a disturbing and degrading experience, while most men see retirement as a rather benign condition of life.

BEREAVEMENT

Although the loss, through death, of loved ones (*bereavement*) can occur at any stage of the life cycle, it becomes more likely as we get older. The psychological and bodily reactions that occur in people who suffer bereavement are called *grief*. The 'observable expression of grief' (Parkes & Weiss, 1983) is called *mourning*, although this term is often used to refer to the social conventions surrounding death (such as funerals and wearing black clothes).

Approaches to the understanding of grief

According to Archer (1999), grief has been variously depicted as (a) a natural human reaction; (b) a psychiatric disorder; and (c) a disease process. All three approaches contain an element of truth. As far as (a) is concerned, grief is a *universal* feature of human existence, found in all cultures. But its form and the intensity of its expression vary considerably (see page 679). As far as (b) is concerned, although grief itself has never been classified as a mental disorder:

> The psychiatric framework emphasises the human suffering grief involves, and therefore provides a useful balance to viewing it simply as a natural reaction ... (Archer, 1999)

Regarding (c), although there may be increased rates of morbidity (health deterioration) or mortality (death) amongst bereaved people, these aren't necessarily directly caused by the grief process. For example, the effects of change in lifestyle (such as altered nutrition or drug intake), or increased attention to physical illness which predated the bereavement, might be mistaken for the effects of grief itself. However, there's substantial evidence that bereaved spouses are more at risk of dying themselves compared with matched non-bereaved controls. This is true mainly for widowers (Stroebe & Stroebe, 1993), and especially for younger widowers experiencing an unexpected bereavement (Smith & Zick, 1996).

Mourners at a Western funeral

Stage or phase accounts of grief

According to Archer (1999), a widely held assumption is that grief proceeds through an orderly series of stages or phases, with distinct features. While different accounts vary in the details of particular stages, the two most commonly cited are those of Bowlby (1980) and Kübler-Ross (1969).

Box 39.6 Bowlby's phase theory of grief

According to Bowlby (1980), adult grief is an extension of a general distress response to separation commonly observed in young children (see Chapter 32). Adult grief is a form of *separation anxiety* in response to the disruption of an attachment bond.

Phase of numbing: Numbness and disbelief, which can last from a few hours up to a week, may be punctuated by outbursts of extremely intense distress and/or anger.

Yearning and searching: These are accompanied by anxiety and intermittent periods of anger, and can last for months or even years.

Disorganisation and despair: Feelings of depression and apathy occur when old patterns have been discarded.

Reorganisation: There's a greater/lesser degree of recovery from bereavement and acceptance of what's occurred.

Kübler-Ross' stage theory: anticipatory grief

Kübler-Ross' (1969) stage view was based on her pioneering work with over 200 terminally ill patients. She was interested in how they prepared for their own imminent deaths (*anticipatory grief*), and so her stages describe the *process of dying*. But she was inspired by an earlier version of Bowlby's theory (Parkes, 1995) and her stages were later applied (by other researchers) to *grief for others*. Her theory remains very influential in nursing and counselling, both with dying patients and the bereaved (Archer, 1999).

Box 39.7 Kübler-Ross' stages of dying

Denial ('No, not me'): This prevents the patient from being overwhelmed by the initial shock. It may take the form of seeking a second opinion, or holding contradictory beliefs.

Anger ('It's not fair – why me?'): This may be directed at medical staff and other healthy people who'll go on living.

Bargaining ('Please God let me ...'): This is an attempt to postpone death by 'doing a deal' with God (or fate, or the hospital), much as a child might bargain with its parents in order to get its own way.

Depression ('How can I leave all this behind?'): This is likely to arise when the patient realises that no bargain can

be struck, and that death is inevitable. S/he grieves for all the losses that death represents.

Acceptance ('Leave me be, I am ready to die'): Almost devoid of feelings, the patient seems to have given up the struggle for life, sleeps more and withdraws from other people, as if preparing for 'the long journey'.

Almost all the patients she interviewed initially denied they had life-threatening illnesses, although only three remained in a constant state of denial (the rest drifted in and out). Denial was more common when someone had been given the diagnosis in an abrupt or insensitive way, or if they were surrounded by family and/or staff who were also in denial. Searching for a second opinion was a very common initial reaction, representing a desperate attempt to change the unpredictable world they'd just been catapulted into, back into the world they knew and understood (March & Doherty, 1999).

Depression is a common reaction in the dying. For example, Hinton (1975) reported that 18 per cent of those who committed suicide suffered from serious physical illnesses, with 4 per cent having illnesses that probably would have killed them within six months. Terminally ill patients suffer from what Kübler-Ross called *preparatory depression* (as opposed to *reactive*).

Elderly people who've lived full lives have relatively little to grieve for – they've gained much and lost few opportunities. But people who perceive lives full of mistakes and missed opportunities may, paradoxically, have *more* to grieve for as they begin to realise that these opportunities are now lost forever. This resembles Erikson's despair (see above), as does *resignation*, which Kübler-Ross distinguished from acceptance. The detachment and stillness of those who've achieved acceptance comes from calmness, while in those who've become resigned it comes from despair. The latter cannot accept death, nor can they deny its existence any longer (March & Doherty, 1999).

Box 39.8 Ramsay and de Groot's nine components of grief

Shock: This is usually the first response, most often described as a feeling of 'numbness', which can also include pain, calm, apathy, depersonalisation, and derealisation. It's as if the feelings are so strong that they're 'turned off'. This can last from a few seconds to several weeks.

Disorganisation: This can be the inability to do the simplest thing, or, alternatively, organising the entire funeral and then collapsing.

Denial: Behaving as if the deceased were still alive is a defence against feeling too much pain. It's usually an early feature of grief, but one that can recur at any time. A common form of denial is searching behaviour (e.g. waiting for the deceased to come home, or having hallucinations of them).

Depression: This emerges as the denial breaks down but can occur, usually less frequently and intensely, at any point during the grieving process. It can consist of either 'desolate pining' (a yearning and longing, an emptiness interspersed with waves of intense psychic pain) or 'despair' (feelings of helplessness, the blackness of the realisation of powerlessness to bring back the dead).

Guilt: This can be both real and imagined, for actual neglect of the deceased when they were alive, or for angry thoughts and feelings.

Anxiety: This can involve fear of losing control of one's feelings, of going mad, or more general apprehension about the future (changed roles, increased responsibilities, financial worries, and so on).

Aggression: This can take the form of irritability towards family and friends, outbursts of anger towards God or fate, doctors, nurses, the clergy or even the person who's died.

Resolution: This is an emerging acceptance of the death, a 'taking leave of the dead and acceptance that life must go on'.

Reintegration: This involves putting acceptance into practice by reorganising one's life in which the deceased has no place. However, pining and despair may reappear on anniversaries, birthdays, and so on.

An evaluation of stage theories of grief

- Generally, stage models haven't been well supported by subsequent research. Both Bowlby's and Kübler-Ross' accounts were proposed before any prolonged, detailed follow-up studies of bereaved people had been undertaken (Archer, 1999).
- According to March & Doherty (1999), they represent generalisations from the experience of some individuals and lack the flexibility necessary to describe the range of individual reactions. Grief *isn't* a simple, universal process we all go through (Stroebe *et al.*, 1993).
- Some researchers prefer to talk about the *components of grief*. Ramsay & de Groot (1977), for example, have identified nine such components, some of which occur early and others late in the grieving process.
- However, many stage theorists have explicitly *denied* that the stages are meant to apply equally and rigidly to everyone. For example, Bowlby (1980) himself said that:

  > These phases are not clear-cut, and any one individual may oscillate for a time back and forth between any two of them ...

- Yet stages provide us with a framework or guidelines for understanding the experiences of bereaved and dying individuals, while at the same recognising that there's a huge variability in the ways individuals react. Stages don't prescribe where an individual 'ought' to be in the grieving process (March & Doherty, 1999).

Cultural influences on reactions to bereavement

Because of the huge individual variability, trying to distinguish 'normal' from 'abnormal' grief seems quite arbitrary (Schuchter & Zisook, 1993). According to Middleton *et al.* (1993), the validity of the concept of *pathological grief* must be considered in terms of *cultural norms.* Although grief is a universal response to major loss, its meaning, duration and how it's expressed, are all culturally prescribed.

Inter- and intra-cultural differences

Cultures differ in how they define death and appropriate expressions of grief. According to Rosenblatt (1993):

> Culture is such a crucial part of the context of bereavement that it is often impossible to separate an individual's grief from culturally required mourning.

For example, in cultures that believe 'do not grieve because grief will cause the ghost of the deceased to take you away' or 'do not grieve because the deceased has gone to a better life', it's difficult to assess accurately what appears to be muted or restrained grief. Similarly, when the 'rules' say 'cry', and people cry, how do we know the grief is genuine, deeply felt and likely to occur in the absence of the cultural demands for crying.

The Jewish rites of mourning are believed to be of therapeutic benefit, enabling the expression, rather than the repression, of grief. For the first few days following a burial, mourners are expected to be distressed and their despair is recognised and supported by relatives and friends who come to pay their respects.

By contrast, the Hindu, Sikh, Muslim and Buddhist religions all discourage too much weeping (Firth, 1993). The Hindus believe that weeping makes a river which the soul of the deceased has to cross, and Sikhs believe the deceased has gone to God. However, the expression of grief is less inhibited in villages on the Indian sub-continent compared with Sikhs and Hindus living in Britain. Similarly, wailing is still very common among Muslims in Muslim countries (Firth, 1993).

Compared with western women, Japanese women accept their husbands' death with composure and resignation. They believe strongly in an afterlife, and that their ancestors are always with them. Their beliefs mitigate feelings of complete loss and, to this extent, they have less to grieve about. The long-lasting grief and depression observed among the bereaved in the UK is partly a result of the lack of rituals and beliefs, as well as the lack of an externally based end to the grieving process (March & Doherty, 1999).

Box 39.9 Culture and the length of the grieving process

- In traditional Navajo Indian culture, the expression of grief lasts for four days following the death (March & Doherty, 1999).
- For Hindus in India, the mourning period lasts 10–16 days.
- For orthodox Jews, there are five graduated periods of mourning: (i) between death and the burial (which occurs as soon as can be arranged); (ii) immediate postburial; (iii) seven days following the burial (the *shiva* week); (iv) 30 days from the burial (marking the official end of mourning, unless it's a parent who's died, in which case it continues for a whole year); finally (v) between 30 days and one year, when the memorial stone is erected (Katz, 1993).

The degree to which weeping is acceptable or encouraged at funerals varies between religious and cultural groups

According to Firth (1993), all the major religions of the world teach that there's some sort of continuity or survival after death. They also comfort and reassure the bereaved by helping to make sense of death and personal loss, providing shape and meaning to the grieving process. As Box 39.9 shows, mourning lasts for a clearly defined period in different cultures, providing 'milestones'. These allow the bereaved a gradual time to let go of the deceased and adjust to the psychological and social changes in their lives.

As well as differences between cultures, there are also important differences *within* culturally diverse countries, such as the USA and the UK. For example, WASP (white Anglo-Saxon Protestant) Americans tend to 'psychologise' their emotional pain (e.g. depression), while people in many ethnic minority groups tend to 'somatise' theirs (e.g. bodily symptoms: Kleinman & Kleinman, 1985).

CONCLUSIONS

The different meanings of 'old' suggest that chronological age is a poor indicator of what a particular elderly individual is like, either psychologically or socially. However,

major theories of social adjustment to old age, such as SDT and AT, tend to regard the elderly as basically all the same. This implies that there's a particular way of ageing successfully, a view not shared by other theories and not supported by research evidence.

Similarly, the view that ageing inevitably involves rapid and generalised cognitive decline isn't supported by research evidence. Both intelligence and memory have many facets, which tend to decline at very different rates.

Retirement is a socially imposed loss of work, which has both social and psychological effects, as does bereavement. Attempts to identify stages of grief that apply equally to everyone have proved largely unsuccessful, partly because of individual variability and partly because of both inter- and intra-cultural differences in how death and grief are understood and managed.

According to Voss (2002):

> ... Older people may not feel old; they may not feel any different than they did during their younger years. They simply face life from an angle that bears the shadow of death more acutely than before. This provides them with an insight unavailable to others and the wisdom not yet achieved by those trying to help them. Acknowledging this is an invaluable part of promoting the respect that older people deserve as fellow human beings ... we should ... help older adults to welcome integrity and wisdom, in whatever form, at the conclusion of their winter years.

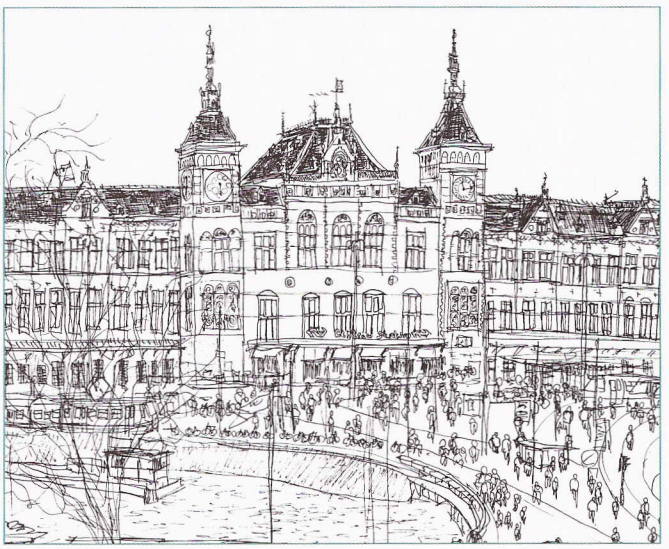
CHAPTER SUMMARY

- While 'growing up' has positive connotations, 'growing old' has negative ones, reflecting the **decrement model**. An alternative, more positive view, is the **personal growth model**.
- One feature of **ageism** is the assumption that **chronological age** is an accurate indicator of **biological**, **subjective**, **functional** and **social age**. **Stereotypes** of the elderly are deeply rooted in rapidly changing western societies, where their experience and wisdom are no longer valued.
- The aged are a collection of **subgroups**, each with its own problems and capabilities. We need to change our stereotypes of the elderly as being needy, non-productive, and unhappy.
- The claim that intelligence declines fairly rapidly in old age is based on **cross-sectional studies**, which suffer from the problem of the **cohort effect**. **Longitudinal studies** indicate that while **crystallised intelligence** increases with age, **fluid intelligence** declines for all age groups over time.
- Some aspects of **memory** decline with age, perhaps due to less effective **information-processing**. Older adults generally perform more poorly than younger adults on **recall** tests, but the differences are much smaller when **recognition** tests are used.
- Evidence from the **OPTIMA project** suggests that **dementia** (such as **Alzheimer's disease**) isn't an accelerated form of normal ageing. Rather, it appears to reflect a **disease process** which is more likely to affect us as we get older.
- **Negative cultural stereotypes** of ageing actually cause memory decline in the elderly, and may become **self-fulfilling prophecies**.
- The most controversial claim made by **social disengagement theory** (SDT) is that the elderly accept and even welcome disengagement, and that this is a natural and inevitable process.
- SDT emphasises the **quantitative** changes to the exclusion of the **qualitative** changes, which may become more important with age. The latter include **friendships**, which are under the older person's control and provide essential informal support.
- **Activity or re-engagement theory** (AT) claims that older people are psychologically and socially essentially the same as middle-aged people. The withdrawal of society and the individual isn't mutual, and optimal ageing involves maintaining the activities of middle age for as long as possible.
- According to **social exchange theory** (SET), older people in industrialised societies have few power resources to exchange in everyday social interaction, making them dependent on others. But the elderly relinquish their roles as economically active members of society in exchange for increased leisure time and fewer responsibilities.
- **Socioemotional selectivity theory** (SST) maintains that for the elderly, **emotional regulation** assumes major importance, making them highly selective as regards social partners. This change in social motives is largely determined by **construal of the future**.
- According to Erikson's **psychosocial theory**, old age involves a conflict between **ego-integrity** and **despair**. The task of ageing is to assess and evaluate life's value and meaning. Despair is characterised by a fear of death.
- **Retirement** is an inevitable, **anticipated** loss of work. People who retire **voluntarily** have little or no difficulty in adjusting, compared with those who are forced to retire. It's the **transition** between employment and retirement that causes adjustment problems.
- Compared with **unemployment**, retirement has an accepted and honourable social status and is a proper reward for a hard life's work.
- **Grief** has been portrayed as a **natural**, **universal human reaction** to bereavement, a **psychiatric disorder**, and a **disease process**.
- **Stage theories** have been criticised on the grounds that grief isn't a simple, universal process which is the same for everyone. However, stages provide a **framework** for understanding bereaved people's experiences, which display a **huge variability**.
- Although grief is a universal response to major loss, its meaning, duration and expression are all **culturally prescribed**. Cultures differ in how they define death,

and it's often impossible to separate an individual's grief from culturally required mourning.

- All the world's major religions teach that there's some kind of **after-life**. They also comfort the bereaved by helping to make sense of death and by providing '**milestones**', which allow a gradual time to adjust to life without the deceased.

Links with other topics/chapters



- Ageism is one of the '-isms' that refer to *prejudiced attitudes* and *discriminatory behaviour* (Chapter 25).
- As with other prejudiced attitudes, *stereotypes* of the elderly form the cognitive component, helping to make the world more predictable and 'controllable' (Chapter 22).
- Measured intelligence is expressed as an *intelligence quotient* (IQ). This measures an individual's standing *relative* to some comparison group (such as people of a similar age). So, while *raw scores* on a test of general intelligence decline with age, one's IQ doesn't (Stuart-Hamilton, 2000, 2003) (Chapter 41).
- *Expert chess players* show better memory than non-experts for actual (possible) chess positions, but there's no difference between them if the pieces are placed randomly (Chapter 20). Based on their greater experience, elderly players may be displaying a similar superiority when they perform as well as younger opponents (Chapter 20).
- The distinction between *recall* and *recognition memory* is important for demonstrating that 'memory-as-retrieval' can mean different things. The greater similarity of performance between younger and older participants is what we'd predict from the greater sensitivity of recognition (Chapter 17).
- The loss of personal identity through loss of access to personal (*autobiographical*) memories suffered by Alzheimer's patients is also experienced by some *amnesic patients* who suffer damage to their *hippocampus*. But the latter don't suffer the general – and eventually fatal – neurological deterioration faced by Alzheimer's sufferers (Chapter 17).
- The theme of continuity between early experience and later personality/relationships is central to understanding *attachments*, including Bowlby's attachment theory (Chapter 32), as well as being a key feature of Freud's *psychoanalytic theory* (Chapters 2 and 46).
- SET in the context of ageing has a rather different meaning from the one it has in the context of *interpersonal relationships/attraction*. Here, it involves a *giving up* of active-adult status in return for benefits of an 'old-age' status. In discussion of relationships, individuals exchange rewards that will determine how much each partner wishes to stay (Chapter 28).
- The greater risk of death amongst widowers (compared with widows) is consistent with findings relating to the greater benefits of *marriage* for men and their greater difficulty in adjusting to *divorce* (Chapter 38).
- Traditionally, a distinction has been made between *reactive* (*neurotic*) and *endogenous* (*psychotic*) *depression*, although this is now much more controversial and less commonly made (Chapter 44).

APPLICATION

EXCEPTIONAL DEVELOPMENT

INTRODUCTION AND OVERVIEW

Sufiah Yusof began a maths degree at Oxford University in 1997 at the age of 13, becoming one of the youngest ever undergraduates in the UK. A few years earlier, Ruth Lawrence graduated with a first class degree from Oxford – she was also 13. At 14, Alexander Faludy became one of the youngest ever people to win a place at Cambridge University. With an IQ of 178 (see Chapter 41), he can deliver verbal dissertations of enormous range and complexity, but he can write only two (illegible) words a minute: he's dyslexic (Martin, 2000).

The drawing above of Central Station, Amsterdam, was done by Stephen Wiltshire, who, as well as having extraordinary artistic skill, is autistic. Recent UK research suggests that a certain proportion of children with Down's syndrome may also be autistic.

What do all these cases have in common? They are all *exceptional*, in the sense of *atypical* (see Chapter 43). The average age for becoming an undergraduate is 18, most undergraduates don't have IQs anywhere close to 178, most people aren't dyslexic, or autistic, nor do they have the artistic (or other exceptional) abilities demonstrated by Stephen Wiltshire and other *savants* (or *idiots savants* as they used to be called). Down's syndrome occurs in about 100 per 100,000 live births (Carpenter, 1997).

'Exceptional' usually implies 'exceptionally bright' or 'unusually gifted', but these various examples illustrate the more accurate sense of 'exceptionally different'. However:

> It is very easy, when dealing with an atypical child, to be overwhelmed by the sense of differentness. But as Sroufe and Rutter and all the other developmental psychopathologists are beginning to say so persuasively, the same basic processes are involved. (Bee, 2000)

To emphasise the differences implies that 'ordinary' and 'exceptional' are *qualitatively different*, while to look for common processes implies that the differences are merely *quantitative*. The examples also illustrate that different types of exceptional abilities (e.g. very high IQ and dyslexia) can be fousnd together *in the same individual*.

GIFTEDNESS

What do we mean by 'gifted'?

According to Smith *et al.* (1998):

> A child may be described as 'gifted' who is outstanding in either a general domain (such as exceptional performance on an intelligence test) or a specific area of ability, such as music, or sport ....

However, the borderline between gifted children and others isn't clearly defined, and different researchers have used different criteria. In Winner's (1998) view, gifted children and child *prodigies* (who are just extreme versions of gifted children) differ from average and bright children in three ways:

1. they're *precocious* – they master subjects earlier and learn more quickly
2. they 'march to their own drummers' – they make discoveries on their own and can often solve problems intuitively, without going through a series of logical, linear steps
3. they're driven by 'a rage to master' – they have an intense interest in the area or domain in which they excel, and can readily focus so intently on work in this domain that they lose sense of the outside world.

They also seem to have unusually good *metacognitive skills:* they know what they know and don't know, and spend more time than average-IQ children planning how to go about solving a problem (Bee, 2000). They seem to teach themselves to read as toddlers, breeze through college maths in middle school, and draw more skilfully at age seven than most adults:

> Their fortunate combination of obsessive interest and an ability to learn easily can lead to high achievement in their chosen domain. But gifted children are more susceptible to interfering social and emotional factors than once was thought ... (Winner, 1998)

KEY STUDY 40.1 Gifted Termites (Terman, 1925; Terman & Ogden, 1959; Holahan, 1988)

- The most famous study of giftedness is Terman's Stanford longitudinal study, which began in 1921.
- Based on his definition of giftedness as an IQ score of around 140 (on the Stanford–Binet test: see Chapter 41), 643 Californian ten-year-olds (the 'Termites') were first nominated by their teachers and then their intelligence was assessed. Their mean score was 151, with a range of 130–190 (only 22 scored below 140).
- They were followed up at various points for much of their lives.
- Their physical health and growth were superior from birth onwards, they walked and talked early, and excelled in reading (which they learnt to do before starting school), language, and general knowledge. Their parents described them as insatiably curious and having superb memories.
- By 1947 (average age 35), their initial level of intelligence had been maintained. 68 per cent had graduated from college, and many were already enjoying outstanding careers. By 1959, this occupational achievement continued. For example, 70 had been listed in the *American Men of Science*, and three were members of the highly prestigious National Academy of Science. In addition, 31 were listed in the *Who's Who in America*, and ten appeared in the *Directory of American Scholars*.

(Based on Smith *et al.*, 1998; Sternberg, 1990; Winner, 1998)

An evaluation of Terman's study

Terman's study showed that gifted children are, perhaps not surprisingly, highly likely to become successful adults. However, the sample of children was biased in at least two important ways (Winner, 1998).

1. Working-class and ethnic minority children were under-represented. Almost one-third of the children

came from middle-class, professional families, so that at least some of their success may have been due to social-class factors as well as to their high IQs.

2. Children participated in the study only if nominated by their teachers, who probably overlooked those gifted children who were misfits, loners or difficult to teach. It was these same admiring teachers who gave such glowing evaluations of their social adjustment and personality.

Terman described the children as superior not just intellectually, but also in terms of their health, social adjustment and moral attitude. According to Winner, this helped create the myth that gifted children are happy, well-adjusted by nature, requiring little special attention, and easy-to-teach. The myth persists despite more recent evidence to the contrary.

Charlotte Church singing at the first inauguration of President Bush in 2001

Some disadvantages of giftedness

Children with exceptionally high abilities in any area (including the visual arts, music and athletics) are out of step socially with their peers. They tend to be highly driven, independent in their thinking and introverted. They spend an unusual amount of time alone and, although deriving pleasure and energy from their solitary mental lives, they also report feeling lonely. The more extreme the level of giftedness, the more isolated they feel (Winner, 1998).

It's been estimated that 20–25 per cent of profoundly gifted children have social and emotional problems (about twice the normal rate), while the moderately gifted show the average rate. By mid-childhood, they often try to hide their abilities in the hope of becoming more popular. One group particularly at risk for such underachievement is that of academically gifted girls, who report more depression, lower self-esteem and more psychosomatic symptoms than academically gifted boys.

ASK YOURSELF...

- Why do you think this sex difference might occur?

CASE STUDY 40.1 Sufiah Yusof

- As mentioned in the *Introduction and overview*, Sufiah Yusof became an Oxford University maths undergraduate at the age of 13.
- She made the headlines in the summer of 2000, when she disappeared shortly after completing her final exams. After the police found her, they took the unusual step of revealing that Sufiah had requested that her whereabouts should remain secret – even (especially) from her parents. Earlier in the week that she was found, she sent her family an e-mail, in which she declared:

  I've finally had enough of 15 years of physical and emotional abuse ...

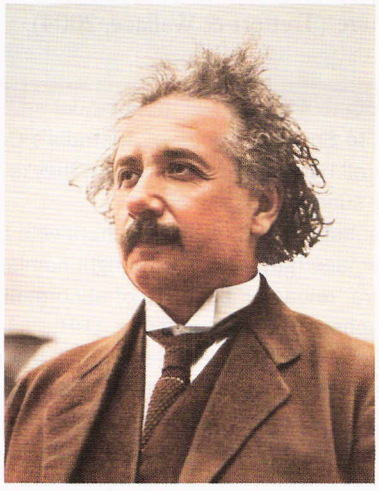
- She vowed never to return to the 'living hell' of home. She accused her father of ruining his five children's lives by brainwashing and *hothousing* them; in her father's words: 'The goals were to prove that you can accelerate children's learning process ... one can nurture and accelerate learning programmes'.
- At 11, she had twice attempted suicide.

(Based on Hattenstone & Brockes, 2000)

Sufiah Yusof pictured in Oxford in 1998 with her father, Farooq

While Sufia's case may not be typical, it's not unique. There are some striking parallels between Sufia's case and that of Ruth Lawrence (see *Introduction and overview*).

Gross (1993) describes the case of Ian. At age five, he hated school, was uncontrollable in class, aggressive towards other children, and was referred to a special school for behaviourally disturbed children. He was found to have an IQ of over 170 (on the Stanford–Binet)



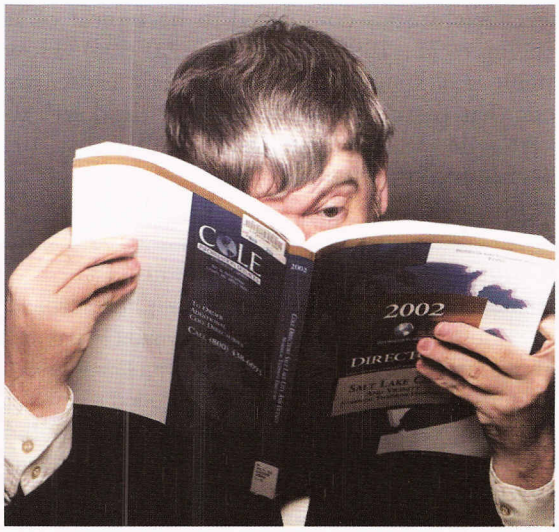
and a reading age of 12. At age nine, his IQ was 200, but his school insisted that he follow the curriculum designed for nine-year-olds. This raises crucial questions regarding how gifted children in general should be educated (see Box 40.1, page 689).

Other researchers (e.g. Gottfried *et al.*, 1994), however, maintain that gifted children have about the same risk of social and emotional problems as normal-IQ children, so that most are well adjusted and socially adept. But the profoundly gifted (e.g. IQs over 180) are so different from their peers, they're likely to be seen as strange and disturbing. They have difficulty finding others who can play at their level (Bee, 2000).

The unevenness of giftedness

Certain gifted children can leap years ahead of their peers in one area, yet fall behind in another. These *unevenly gifted* children sometimes seem hopelessly out of sync. Terman promoted the view that gifted children were *globally* gifted, that is, evenly talented in all academic areas. Indeed, some children do fit this stereotype of the all-round high-achiever. However, many display giftedness in one area but are unremarkable, or even disabled, in others. These may be creative children who are difficult in school, and not immediately recognised as gifted.

This unevenness is quite common. Winner (1998) cites a survey of over 1000 highly academically gifted adolescents, which found that over 95 per cent had a strong disparity between mathematical and verbal abilities. Extraordinarily strong mathematical and spatial abilities often accompany average or even deficient verbal skills. A good example is Albert Einstein, who was sacked from two teaching jobs for terrible spelling, and once said: 'If I can't picture it, I can't understand it'. Similarly, Thomas Edison, inventor of the light bulb and phonograph, had spelling, grammar, and learning problems ('I almost decided I must be a dunce', he once admitted). Even Leonardo da Vinci had erratic spelling, and scribbled notes backwards (Martin, 2000).



Albert Einstein (1879–1955), unevenly gifted

Savants

Many children who struggle with language may have strong spatial skills, and the association between verbal deficits and spatial gifts seems especially strong among visual artists. The most unevenly gifted of all are the *savants,* such as Stephen Wiltshire.

The term 'idiots savants' was first used by Langdon Down (best known for having identified Down's syndrome) in 1887 to describe the coexistence in some individuals of low general cognitive functioning and above-average specific ability. They appear to be able to use processing strategies within a particular domain that seems independent of their general level of intelligence. While recognised for almost 200 years, savants were reported mainly in the form of descriptive case histories.

Savant syndrome and autism

Kim Peek

Savant syndrome is seen in about one in ten people with autism, and in approximately one in 2000 people with brain damage or mental retardation. Of the known savants, at least half are autistic, and the rest have some other kind of developmental disorder (Treffert & Wallace, 2004). The syndrome generally occurs in people with IQs between 40 and 70 – although it can occur in some with IQs up to 114 or over. It disproportionately affects males (four to six males for every female).

The skills involved in savant syndrome are rather limited in their range, restricted mainly to *right-hemisphere* non-symbolic, artistic, visual and motor abilities. They include music, art, maths and various forms of calculating (such as calendar-counting). For example, Kim Peek can tell you what day of the week you were born on and on what day you'll celebrate your 65th

birthday. Despite being developmentally disabled, he knows more than 7600 books by heart, as well as every area code, highway, zip code and television station in the USA. He provided the inspiration for Dustin Hoffman's character Raymond Babbit in *Rain Man* (1988) (Treffert & Wallace, 2004).

In 1983, O'Connor and Hermelin began a series of systematic, controlled experimental studies with groups of musical, calendar-calculating, and artistic savants. Their main aim was to find out why there was a marked frequency of individuals with autism in the savant population.

In discussing Stephen Wiltshire, Sacks (1995) asked whether one could speak of a 'distinctive autistic art'. He points to the concreteness, detailed perceptual accuracy, and the 'thisness' of Stephen's drawings of cars and buildings, with which he's preoccupied. At art school, he displayed an exceptional ability to depict space and distance in perspective (Pring & Hermelin, 1997). Such a remarkable focusing on perceptual details of a display, and on their accurate reproduction, are reminiscent of some of the characteristics considered to be typical of autism (Hermelin *et al.*, 1999: see pages 690-696). However, Hermelin *et al.*'s study of several autistic artists strongly suggests that there's no stereotyped 'autistic art'; that is, their art reflects true artistic talent rather than being a manifestation of their autism.

CASE STUDY 40.2 Richard (Hermelin *et al.*, 1999)

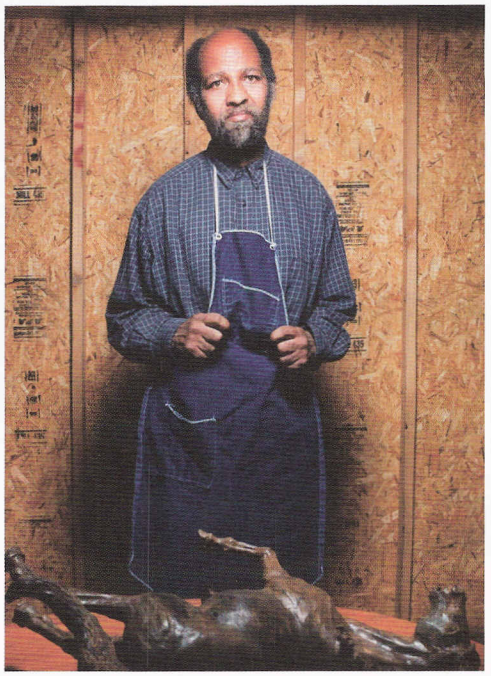
- Richard (born 1952) is autistic, mentally handicapped, and suffers from a severe congenital visual impairment: he's extremely myopic and has glaucoma (increased pressure in the eye) which is well controlled by medication. His verbal IQ is 47, and his non-verbal IQ is 55. He began to draw at the age of four, and now uses exclusively oil-based coloured crayons on paper.
- He doesn't look at other artists' work, but goes to the local library and studies landscape photographs and brochures in the travel agency. Days, weeks, or even months later he'll reproduce one of these pictures from memory. Sometimes he'll draw a natural setting he's looked at through binoculars. He's had many exhibitions all over the world, and he earns a living as a professional artist.
- Based on a comparison between his drawings and the photographs they're often based on, an art expert judges him to display true artistic talent. Moreover, like Cézanne and Monet, who were both myopic, Richard's visual impairment may have worked to his advantage. Hermelin *et al.* suggest that:

  It relieves an individual from direct precise visual input and by necessity gives him the freedom to impose his own distorted image, thus generating his own representation of reality.

CASE STUDY 40.3 Hikari Kenzaburo

- Hikari was born in 1963 with a growth on his brain that made him look as if he had two heads. He was severely autistic, had constant seizures, and poor vision. He could fly into rages and needed constant attention, patience and reassurance. He never cried and didn't seem ever to dream.
- Yet even as a toddler, he'd listen, enthralled, to music, and to bird-song. His parents encouraged this sign of imagination, feeling that music could perhaps reach and touch him as nothing else could. In fact, Hikari could also express himself and reach others through music.
- While words are blunt and hopeless tools, he can compose musical works for violin and piano, which his father describes as a 'wailing soul', embodying a 'core of sorrow'.

(Based on Gerrard, 1996)



A biological explanation: the left hemisphere hypothesis (LHH)

The most powerful currently available explanation of savant syndrome claims that some injury to the left hemisphere of the brain causes the right hemisphere to *compensate* for the loss. As we've seen, savant abilities are predominantly *right hemisphere,* which is consistent with the LHH. Also consistent with the LHH is Baron-Cohen's (2003) *Empathising-Systemising* (E-S) *theory* of autism, according to which autistic individuals have extreme *male brains* (that is, brains that are hardwired for *right-hemisphere* skills and abilities: see below). Further support comes from the study of elderly patients with *frontotemporal dementia* (FTD), a form of pre-senile dementia (see Chapter 39). Some of these patients suddenly develop artistic skills they didn't previously possess, and all of them show damage on the *left* side of the brain. They become savant-like (visually creative: a right-hemisphere ability) as dementia takes hold in their left hemisphere (Treffert & Wallace, 2004).

Research update 40.1 Are we all potential savants?

- According to Snyder (director of Australia's Centre for the Mind), we all have amazing skills, but they're concealed within our subconscious mind.
- In some autistic individuals and others with left-hemisphere damage (savants), these (right-hemisphere) abilities are 'released' because of abnormalities in the left hemisphere (as claimed by the LHH).
- In addition to people suffering from FTD, there are cases of savant skills appearing suddenly in people following brain damage. For example, one ten-year-old child suddenly acquired spectacular calendar-calculating skills and an extraordinary memory for dates and music following an injury to the left side of the head. Another

famous case is Alonzo Clemons, who developed a striking talent for animal sculpture following a childhood head injury (Phillips, 2004b).

Alonzo Clemons can create perfect wax replicas of any animals he sees, no matter how briefly

- It follows that if you can reduce or stop electrical activity in the left hemisphere, it might be possible to unlock the 'little Rain Man in each of us' (Treffert & Wallace, 2004).
- Snyder has attempted this, using a technique called *repetitive trans-cranial magnetic stimulation* (rTMS). This is used routinely in neurology departments and hospitals as a research tool to test for side-effects of brain surgery, and to establish the function of different brain regions. It basically uses a strong magnetic field to switch off activity in the nearby part of the brain.

A TMS machine

- Snyder's initial results were published in 2003. Only four out of eleven participants responded, but in those four there were some notable effects in their drawing style and their ability to spot non-obvious mistakes in written prose. Other researchers have replicated Snyder's findings (Phillips, 2004b).
- Treffert and Wallace (2004) agree with Snyder's claims, concluding that:

  ... all of us have some of the same circuitry and pathways intrinsic to savant functioning but ... these are less accessible – in part because we tend to be a left-brain society. Sometimes, though, we can find elements of the savant in ourselves. At certain moments, we just 'get' something or discover a new ability ...

Accounting for giftedness

Brain development and organisation

Non-savant gifted children most likely have atypical brain organisation to some extent too (Winner, 1998). Individuals with pronounced right-hemisphere abilities (maths, music, and art) are disproportionately *non*-right-handed (they're either left-handed or ambidextrous). They also have higher than average rates of left-hemisphere deficits (such as delayed speech onset, stuttering, or dyslexia).

Geschwind and Galaburda (in Winner, 1998) hypothesised that this association of gift and disorder ('the pathology of superiority') results from the effects of testosterone on the developing foetal brain. Raised levels can delay development of the left hemisphere ('testosterone poisoning'), which might in turn produce compensatory right-hemisphere growth. This might also account for the larger number of males than females who display mathematical and spatial gifts, non-right-handedness, and language disorders.

Although this hypothesis is controversial, and there's only scant evidence to support the theory of damage and compensation in savants, Winner (1998) believes that:

... it seems certain that gifts are hardwired in the infant brain, as savants and gifted children exhibit extremely high abilities from a very young age before they have spent much time working at their gift.

ASK YOURSELF...

- In light of the discussion above about the LHH, do you agree with Winner's conclusions?
- Does describing someone as talented help explain his/her exceptional ability?
- If so, where do you think this talent comes from?

The 'talent account': geniuses are born

The quote from Winner above partially defines the 'talent account' of giftedness, the widely held belief that the likelihood of becoming exceptionally competent depends on the presence or absence of inborn attributes ('talents', 'gifts', 'natural aptitudes': Howe *et al.*, 1998). The judgement that someone is talented is believed to help *explain* (not merely describe) that person's success. According to Howe *et al.*, certain assumptions are made about talent:

- it originates in *genetically transmitted structures,* and so is at least partly *innate*
- its full effects may not be evident at an early age, but there will be some advance indications that allow trained people to spot its presence before exceptional levels of mature performance have been shown
- these early indications of talent provide the basis for predicting who's likely to excel
- only a minority is talented – if all children were, we couldn't predict or explain differential success
- talents are relatively *domain-specific.*

For Gardner (1993), talent is a sign of precocious biopsychological potential in a particular domain, such as dance, chess, or maths (see his theory of *multiple intelligences:* Chapter 41). Similarly, Winner (1996) sees talents as unlearned, domain-specific traits that may develop or 'come to fruition' in favourable circumstances – but they cannot be manufactured.

Is the talent account valid?

According to Howe (1999), although it's widely accepted that innate talents can explain how genetic differences between people impact on their capabilities,

> ... there are good reasons for thinking that such talents are mythical rather than real.

Genetic contributions to human activities are complex and indirect (see Chapters 41 and 50). Also, it tends to be assumed that if there are qualities that make some people more capable than others and that have an inherited component, these will be closely related to a person's cognitive attributes (such as cleverness or creativity). But according to Howe (1999):

> ... it is just as likely that those – conceivably largely inherited – human qualities that make the larger contributions towards setting geniuses apart from other people are ones of temperament and personality rather than being narrowly intellectual ones ...

Indeed, the qualities that contemporaries of geniuses such as Newton and Mozart most often remarked on were broadly temperamental: doggedness, persistence, capacity for fierce and sustained concentration, and intense curiosity. Several geniuses, including Darwin and

Portrait of Wolfgang Amadeus Mozart, aged 14 (Blanchet)

Einstein, denied having any superior inherent intelligence (see above), but none has ever denied either possessing or relying on a capacity for diligence and healthy curiosity (Howe, 1999).

People fear that geniuses will be diminished if we remove the mystery or magic surrounding them by denying that they're a breed apart. On the contrary:

> ... it is not until we understand that they are made from the same flesh and blood as the rest of us that we start to appreciate just how wonderfully remarkable these men and women really are. They show us what humankind is capable of ... (Howe, 1999).

Howe *et al.* (1998) reviewed the arguments on both sides. They found no evidence of innate attributes operating in the predictable and specific way they felt 'talent' implies, and concluded that differences in early experiences, preferences, opportunities, habits, training and practice are the real determinants of excellence.

One of the challenges to the talent account has focused on musical genius (e.g. Sloboda *et al.*, 1994a, 1994b). For example, top violinists by the time they're 20 have practised more than 10,000 hours in total (and less successful ones only 5000). This began as early as ages four to six for international performers – about four concentrated hours per day.

According to Sloboda (in Aldersey-Williams, 1999):

> Early ability is not evidence of talent unless it emerges in the absence of special opportunity to learn.

Even that prodigy of prodigies, Mozart, had a composer–father who was also famously ambitious for

his son and bullied him towards musical greatness. Demonstrations of exceptional musical skill tend to *follow* rather than precede attempts to encourage it.

Similarly, Ericsson & Charness (1994) note that the winning time of the first Olympic marathon is comparable to the qualifying time achieved by thousands of runners in the modern Boston marathon.

ASK YOURSELF...
- Try to explain these dramatic changes in runners' capacity.

Greater knowledge about running, better nutrition and medical care, better training techniques and so on can adequately explain these changes, without having to bring genetic factors into it. Similarly, differences between world-class athletes (as with violinists) reflect differences in training and practice from an early age – *not* genetic differences.

ASK YOURSELF...
- Howe *et al.* acknowledge that theirs is an *extreme environmentalist* position, which many would reject. Try to identify some counter-arguments.

Howe *et al.* conclude their review by saying that if excelling is a consequence of possessing innate gifts, there's no point trying to nurture them in children without them:

... categorising some children as innately talented is discriminatory. The evidence suggests that such categorisation is unfair and wasteful, preventing young people from pursuing a goal because of the unjustified conviction of teachers or parents that certain children would not benefit from the superior opportunities given to those who are deemed to be talented.

Box 40.1 How should gifted children be educated?

- Generally, schools focus whatever resources they have on the *moderately academically gifted:* bright students with strong but not extraordinary abilities, who don't face the problems of precocity and isolation to the same degree as the profoundly gifted. The moderately gifted comprise the majority of the current 'pull-out' programmes in American schools (i.e. removal from regular classes).
- The use of IQ as a filter for gifted programmes tends to tip them towards the moderately gifted, at the expense of the profoundly but unevenly gifted children. Many of the latter do poorly on IQ tests, because their talent lies in either maths or language – but not both. Those whose talent is musical, artistic, or athletic are also regularly omitted.
- It makes more sense to identify the gifted by examining past achievements in specific areas, rather than relying on 'plain-vanilla IQ tests' (Winner, 1998). Schools should then place the profoundly gifted in advanced courses only in their areas of giftedness – other subjects can continue to be taught in regular classes.
- Many gifted children are so bored by school that they become disengaged, even dropping out, often because their school districts don't allow grade acceleration or have no special programmes. According to Bee (2000):

  Given ... that grade skipping does not seem to be linked to social maladjustment (and is linked to better achievement among the gifted), it seems to make good sense to encourage accelerated schooling, if only to ward off terminal boredom for the gifted child.

- In England and Wales, Ofsted (the Schools Inspectorate) has highlighted the fact that often the most able pupils in a school aren't receiving a satisfactory education (Alcott, 2002) – their special needs aren't being met. As a result, many gifted and exceptional children may become bored, leading to disruptive behaviour. Schools are now addressing this 'deviant' end of special educational needs (SENs). For example, a useful recent distinction has been made between 'gifted' (those with high levels of ability in many subjects and activities) and 'talented' children (those who excel in only one area). Once identified, both groups are either:

  1. *aggregated* (all the gifted are put together and all the talented together)
  2. *accelerated* (moved up a whole year or two years – 'grade-skipping'), or
  3. *enriched* (given a special educational programme) – an individual learning account is drawn up, usually in response to a *statement of SENs* agreed with the local educational authority; this provides individual children with the most appropriate form of education, which is exactly the same principle as for children with learning difficulties (see text below). But the reality of what's offered may fall short of these sound educational principles (Curtis, 2003).

AUTISM

Definition and classification

Autism was first identified by Kanner in the USA (1943) and Asperger in Austria (1944), quite independently of each other. Kanner used the term 'early infantile autism' ('autos' is Greek for 'self') to describe individuals who had an 'aloneness', which involved the ignoring and shutting out of the world and living in an isolated, essentially asocial state. They were limited in language and obsessive about the need for sameness in particular aspects of their environment. Kanner speculated (incorrectly) that they

fall within the average range of intelligence, and that any poor learning performance resulted from their difficulties with the social aspects of learning.

Asperger worked with an older age-group, but his observations overlapped with Kanner's. He also used the term 'autistic', and there's an ongoing debate as to whether autism and what's now called Asperger's syndrome are distinct disorders, expressions of the same disorder, or both part of an *autistic spectrum* (with those displaying Asperger's constituting a high-IQ subgroup). According to Powell (1999), they aren't mutually exclusive – Asperger's individuals have a particular form of autism (see Box 40.2).

Later, ritualistic and compulsive dimensions were identified as crucial, resulting in the *triad of impairments* (social relationships/behaviour, language/communication, and stereotyped/repetitive behaviour: Wing, 1976). Also, Wing & Gould (1979) found that learning disabilities (LDs) (IQ below 70) were clearly associated with the triad (see Table 40.1, page 697). Ninety per cent of those having 'full', typical autism had an IQ between 20 and 69.

Box 40.2 Autism Spectrum (AS)

- As a result of Wing & Gould's (1979) findings, it became clear that there's a wide spectrum of autistic disorders, of which 'Kanner's autism' is only a part.
- They estimated that 20 children per 10,000 have AS disorders and mental retardation (learning disabilities), a figure that was revised by Wing (1997) to nine per 1000. Does this reflect changes in diagnostic criteria or an increasing prevalence (Powell, 1999)?
- According to Scott (2004), the triad of impairments can be manifested in a wide variety of ways, such that no children with autism are alike – in fact, they can be extremely different. The most widely used manuals of psychiatric classification of disorders (ICD-10 and DSM-IV-TR: see Box 40.3) currently include *autism, atypical autism, Asperger's Syndrome* and *Pervasive Developmental Disorder – Not Otherwise Specified* (PPD-Nos), and others, as part of the AS. It's not clear whether all these disorders are related by underlying cause or only by similar symptoms ('outward appearance') (Scott, 2004).

Incidence and diagnosis

According to Mitchell (1997), the incidence of autism is one to two per 1000 live births, with boys outnumbering girls by four or five to one, at least for those with Asperger's. In the more seriously affected, boys still outnumber girls by two to one. Recent research conducted at the Autism Research Centre, University of Cambridge, shows that 6 per cent of siblings of children with autism will also have problems with all three kinds of impairment, 10–12 per cent will have problems with two or three areas, and a further 20 per cent in one area. If one identical (monozygotic/MZ) twin has autism, there's a 60 per cent chance the other twin will have problems in all three symptom areas, an 80 per cent chance of problems in any two areas, and a 90 per cent chance of problems in any one area. For non-identical (dizygotic/DZ) twins, the figures are the same as for ordinary siblings (Scott, 2004). These percentages are referred to as *concordance rates.*

ASK YOURSELF...

- What do these figures suggest regarding the *causes* of autism? (See Box 40.2.)
- What do they tell us about the autism spectrum?

Box 40.3 Criteria for diagnosing autism (based on DSM-IV-TR)

- **Qualitative impairments in social interaction:** impaired non-verbal behaviours (especially eye contact), failure to engage in genuinely social games (such as turn-taking), no attempt to share interests through *joint-attentional behaviours*, and a failure to develop any friendship beyond the most superficial acquaintance. A lack of empathy is often seen as the central feature of the social deficit (Baron-Cohen, 1988; Kanner, 1943).
- **Qualitative impairments in communication:** failure to develop language and communication in the normal way (such as delayed and restricted language development, stereotyped and repetitive or idiosyncratic use of language), and failure to use gesture properly. Also, a lack of varied, spontaneous make-believe/symbolic play (Leslie, 1987), and engaging in play which is often lacking in creativity and imagination (Baron-Cohen, 1987).
- **Repetitive and stereotyped patterns of behaviour:** an inflexible adherence to specific routines, becoming distressed if prevented from performing repetitive rituals, stereotyped and repetitive motor mannerisms, and persistent preoccupation with parts of objects.

Autism is typically very difficult to diagnose before about age three. Many 'normal' children are slow to develop in their communication, for example, and complex social behaviours are hard to interpret before the child becomes capable of two-way social interactions (Scott, 2004). The CHAT (Checklist for Autism in Toddlers) has been developed by Baron-Cohen and his colleagues as a screening tool for autism at 18 months. It's designed to be used by GPs or health visitors, and involves a short series of parent questions and interviewer observations of the child. So far, the CHAT has been shown to have a 91.7 per cent success rate at identifying cases of autism spectrum disorder at 18 months. The results suggest that absence of pretend play and joint-attention might be the clearest indicators of risk for autism (Scott, 2004).

According to Lewis (2003), most children diagnosed as autistic have LDs, with over half having IQs below 50. Typically, verbal ability is more seriously affected than non-verbal. Consequently, it's important to show that the characteristic behaviours are found across the ability range – otherwise there'd be a risk of confounding autism with LD. For this reason, much research has focused on relatively able autistic children, who are often compared with children with LDs but not autism (such as Down's syndrome children).

Autism and Down's syndrome

Mitchell (1997) identifies some important similarities and differences between autism and *Down's syndrome.*

- Both conditions are present from birth. But whereas Down's is usually evident from the baby's facial appearance (and will often have been detected prenatally, especially with older mothers), autistic babies look perfectly normal and the diagnosis isn't made until the child is aged four or over. If the diagnosis is made later, this doesn't mean they've 'acquired' it at an older age. Rather, a new label has been applied to existing behaviour patterns.

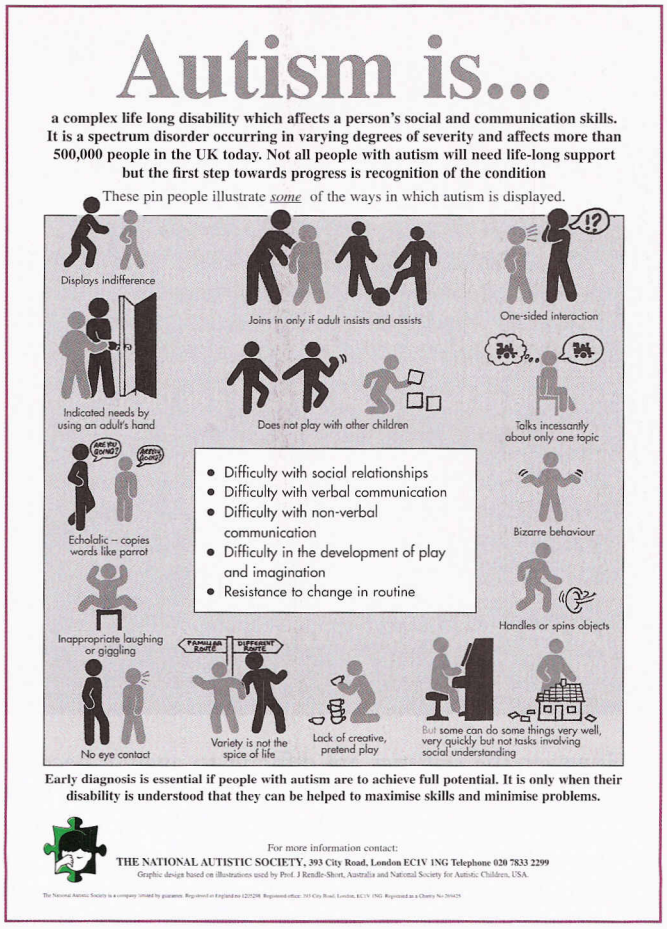


Figure 40.1 From a National Autistic Society leaflet
(Reproduced by permission of the National Autistic Society)

The self-absorption displayed by this autistic girl prevents her from developing a normal 'theory of mind'

- Down's is classified as a chromosome abnormality (the child inherits an extra 21st chromosome) and is the most commonly occurring such abnormality (see Chapter 36). Diagnosis is based on the detection of this extra chromosome, while autism is diagnosed on the basis of characteristic behaviours (see Box 40.3). Relatively little is known about its physiological basis (see Box 40.6, page 695).
- Neither condition can be 'cured', although adaptation and development can and do occur. For example, 50 years ago life expectancy among people with Down's was considerably lower than that of the general population. But the gap has narrowed significantly, mainly because of antibiotics and general improvements in diet, care, and living conditions (Moddia, 1996).

A child with Down's syndrome

- LDs are characteristic of Down's and common in autism (see above). But some autistic individuals have normal IQs, and some (5–30 per cent) may have above-average IQs. With increasing IQ, autism becomes more difficult to diagnose – and may escape diagnosis altogether.
- As we saw when discussing giftedness, many autistic individuals display outstanding musical or artistic abilities (savants). This doesn't occur in individuals with Down's syndrome.

Interestingly, recent research has suggested that about 7 per cent of children with Down's syndrome also have some level of autistic disorder (Kent *et al.*, 1999).

Theories of autism

According to Smith *et al.* (1998):

> The challenge for any researcher investigating autism is trying to explain how one syndrome can lead to the specific combination of impairments which typify a person with autism (lack of socialisation, communication and imagination); how different people with autism can be affected in markedly different ways; and how it is that people with autism can sometimes have better than average abilities in one or two areas (the 'islets of ability').

'Refrigerator parenting' hypothesis

Kanner had originally suggested that autism was partly the result of 'cold', unemotional parenting, specifically by the mother. However, the prevailing current view is that parents' behaviour doesn't initiate or in any way provoke autism. Indeed, any difference in parents' behaviour towards their autistic child is more likely to be caused *by* the autism than vice versa (Powell, 1999).

Also, autism seems to strike indiscriminately. It's no respecter of social class or family environment: it can affect a child with extremely warm and loving parents and where there are no autistic siblings (Mitchell, 1997).

Genetic theories

Kanner originally suggested that autism has a genetic component. According to Rutter *et al.* (1999), findings from several independent studies provide compelling evidence for a strong genetic component underlying autism.

- As we saw earlier, the rate of autism (involving all three problem areas) in siblings of children with autism is 6 per cent. This is many times the rate in the general population (ranging from 1 to 16 per 10,000). Rutter *et al.* maintain that:

  > Whatever the precise figure, it is clear that there is a very substantial degree of familial clustering of autism. Although this could reflect shared environmental factors, a loading as high as this points to the likelihood of a genetic component.

- We also saw earlier that the concordance rate for MZ twins is far higher than for DZ twins. In other words, if one member of a twin pair is autistic, the probability that the other will also be autistic depends to a significant degree on whether they share all their genes (MZs) or only half their genes (DZs: the same as ordinary siblings). Rutter *et al.* believe that several different genes are involved, working in combination: the twin data indicate that autism is the most strongly genetically influenced of all *multifactorial* child psychiatric disorders.

Box 40.4 Where might autistic genes be found?

- Not only have there been reports of an association between autism and anomalies on almost all *autosomal chromosomes* (the non-sex chromosomes), but these are usually based on individual cases. This makes the validity and meaning of the association highly dubious.
- More encouraging is the finding that the portion of chromosome 15 that seems to be implicated in autism is also where the genes for Prader-Willi and Angelman syndromes are located.
- Probably most interest has focused on claims of a strong association between *fragile X syndrome* and autism. Boys have only one X chromosome, so, unlike girls, any defects on it aren't 'cancelled out' by normal genes on the other. Defective genes carried on the X chromosome are the second most common genetic cause of LDs (after Down's syndrome). Affected individuals tend to have prominent jaws and large ears.
- The original claim was that fragile X occurred in at least 16 per cent of autistic individuals, although the accurate figure is almost certainly below 5 per cent. Given the strong male preponderance in autism, it's reasonable to consider that one of the genes that predisposes individuals to autism might be located on the X chromosome.
- Although the International Molecular Genetic Study of Autism Consortium (1998) failed to find any supporting evidence, it did find evidence suggesting the roles of chromosomes 7 and 10, something which hasn't been previously reported.

(Based on Lauritsen *et al.*, 1999; Mitchell, 1997; Rutter *et al.*, 1999)

- However, the statistics are difficult to analyse because autism is still rare, as are MZs, and so the prospects of finding autism in a member of an MZ pair is very remote. Hence, adding just one MZ pair either with or without concordance can radically shift the overall concordance rate (Mitchell, 1997). If autism isn't caused solely by genetic factors, then there must be an environmental component. For example, Piven &

Folstein (1994) found that about 30 per cent of parents with an autistic child show at least some autistic mannerisms, such as deficient turn-taking in conversation, misinterpreting or not noticing implied meanings of their conversational partner's utterances. Parents of Down's syndrome children, as controls, showed no such difficulties.

ASK YOURSELF...
- Why was it necessary to have a control group at all?
- Why do parents of Down's children make a suitable control group?

Theory of mind (ToM) and mind-blindness

The most influential theory of autism in recent years maintains that what all autistic people have in common (the core deficit) is *mind-blindness* (Baron-Cohen, 1990), a severe impairment in their understanding of mental states and in their appreciation of how mental states govern behaviour (e.g. Baron-Cohen, 1993, 1995a, 1995b). They lack a '*theory of mind*' (ToM), a term originally coined by Premack & Woodruff (1978) based on their work with chimps (see Gross, 2003a).

When the ability to 'read minds' is in any way impaired, enormous difficulties arise. Autistic individuals fail to develop the ability to attribute mental states to other people, and this has fundamental implications for communication, where making sense of others' intentions enables the listener to understand what's being said (Baron-Cohen, 1995a).

ASK YOURSELF...
- Try to think of examples of 'mind-reading', either from real-life interactions with others, or from TV programmes, films or literature.
- How vital is it that we take into account the fact that not everyone has access to the same information about a situation?

Testing the ToM hypothesis

Wimmer & Perner (1983) devised a *false belief task,* with four-, six- and eight-year-olds, involving two small dolls (Maxi and his mother). The dolls enact a story in which the mother moves Maxi's chocolate from a green drawer (put there by Maxi) to a blue drawer (while Maxi's outside playing). Children are asked *where Maxi would look for the chocolate* when he returned. A *correct answer* ('green drawer') involves attributing to Maxi a *false belief:* the children *know* the chocolate's in the blue drawer, but they also know that Maxi doesn't have this knowledge (so he thinks it's still in the green drawer). An *incorrect answer* ('blue drawer') indicates that children cannot distinguish between what they themselves know and what Maxi knows. A correct answer reflects a ToM.

KEY STUDY 40.2 Has Sally lost her marbles? (Baron-Cohen *et al.*, 1985)

- This was a replication of the Wimmer and Perner 'Maxi' study, retaining the vital elements but adapted to make it shorter and simpler and more appropriate in content for older children (Mitchell, 1997).
- Sally and Anne replace Maxi and his mother, and the story involves transfer of a marble from a basket to a box.
- A crucial difference between Baron-Cohen *et al.*'s and the Wimmer and Perner study is that the latter involved only normal children. Baron-Cohen *et al.* tested:
  (a) 20 autistic children, chronological age (CA) 6–16 (mean 11.11), mean verbal mental age (vMA) 5.5
  (b) 14 Down's syndrome children, CA 6–17 (mean 10.11), mean vMA 2.11
  (c) 27 normal children, CA 3–5 (mean 4.5), assumed to have vMAs equivalent to their CAs.

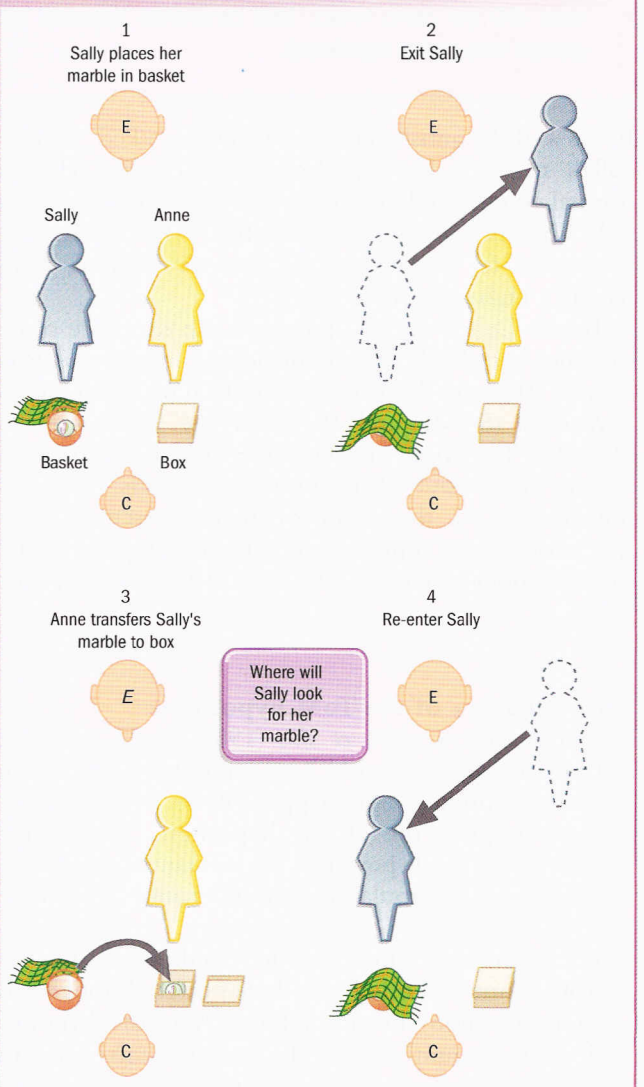

Figure 40.2 The experimental scenario used in Baron-Cohen *et al.*'s (1985) study

ASK YOURSELF...
- Why were these two other groups used?

- The *dependent variable* was success or failure on the Sally–Anne test, specifically, on the question: 'Where will Sally look for her marble?' (*belief question*).

ASK YOURSELF...
- Assuming that autistic children don't possess a ToM, while normal children and those with Down's syndrome do, how would they have answered the question?

- The results for Down's syndrome and normal children were strikingly similar: 23 out of 27 normal children, and 12 out of 14 Down's syndrome children passed the belief question. By contrast, 16 of the 20 autistic children (80 per cent) failed. This difference between the groups was highly significant.

It was as if the autistic children had been asked: 'Where is Sally's marble?' They performed much like clinically normal young children do (i.e. below 4), but their average CA was just below 12 (Mitchell, 1997). They also performed far worse than the Down's children, despite having a higher mean verbal MA.

Baron-Cohen (1995a) proposed the existence of four modules involved in 'mindreading': the *intentionality detector* (ID), *eye-direction detector* (EDD), *shared-attention mechanism* (SAM), and the *theory of mind mechanism* (ToMM). ToMM is innately determined and begins to mature from about 12–18 months to 4 years. It processes information in the form of metarepresentations: it's specialised for representing mental representations ('beliefs about beliefs') (Leslie, 1987, 1994; Leslie & Roth, 1993).

An evaluation of the ToM hypothesis

- Since Baron-Cohen *et al.*'s (1985) study, researchers from all over the world have replicated and extended the basic findings (see Happé, 1994a).
- But despite the ToM hypothesis being both convincing and powerful, a substantial amount of evidence is accumulating that undermines it (Mitchell, 1997).
- For example, some autistic children *do* pass the Sally–Anne and other false-belief tasks, although often later than non-autistic children. Also, the hypothesis doesn't account for *all* the impairments/difficulties associated with autism, such as a restricted range of interest, the obsessive need for sameness and preoccupation with parts rather than the whole (the trees rather than the wood).
- Equally, it fails to address some of the apparent strengths of at least some autistic individuals, such as their excellent rote memory and the exceptional abilities (the 'islets of ability'), as demonstrated by Stephen Wiltshire and other savants (Frith, 1996; Mitchell, 1997; Powell, 1999: see above).

CRITICAL DISCUSSION 40.1 Do people with autism have extreme male brains?

- The limitations of the ToM hypothesis may be at least partially remedied by Baron-Cohen's (2003) *empathising–systemising (E-S) theory*.
- According to Baron-Cohen, people with autism may have an extreme form of the male brain – good at systemising, very bad at empathising.
- The obsessional interests that people with autism spectrum conditions show often focus on a *system*. This may be an intense preoccupation with light switches, or running water from the taps in different sinks. According to E-S theory, the child may simply be focusing on tiny details in the system (for example, how fast the water flows when the tap is turned to different angles) – that is, using their intelligence to work out the *underlying rules* that govern it.
- Typically, they home in on a topic or area of knowledge, and comb it for every detail until they feel they've covered most, if not all, the available information. The 'obsession' can last weeks, months or even years. They then move on to a new area to master. This *systemising* represents a *learning style* that prefers depth to breadth, and accuracy or exactness over gist.
- What's likely to leave them disabled is their *impaired empathising*. This is related to their *mind-blindness*.
- Empathising is controlled by the *left hemisphere* of the brain, and is generally superior in females. Systemising is controlled by the *right hemisphere*, and is generally superior in males. According to E-S theory, people with autism, whether male or female, have an extreme male brain: it's predominantly 'right-sided'.

- Other attempts to correct some of the limitations of the ToM hypothesis include (a) *weak central coherence* and (b) *impaired executive functioning*.

Weak central coherence

Frith (1989; Frith & Happé, 1994a, b) proposed that the deficits and strengths stem from the same cognitive source involving how information is integrated. Specifically, they claimed that autism is at least partly the result of a '*weak drive for central coherence*'.

Box 40.5 Central coherence

- While we normally process information at a *global* (*holistic* or 'top-down') level, autistic individuals tend to do this at a *local* (*segmental* or 'bottom-up') level.

- This corresponds to 'the whole' and 'the parts' respectively (see Chapter 15). The former allows us to *disambiguate* ambiguous words (homographs) within the context of a sentence, something which autistic children couldn't do even if they did succeed at ToM tasks (Frith & Snowling, 1983; Happé, 1994b).
- These same children also tend to have difficulties in real-life situations where ToM is required, since they cannot extract information from its context:

Knowing the theory of how other minds work is simply not enough if that knowledge does not take account of context and in the social world context is all important, ever-changing and often implicit ... (Powell, 1999)

Weak central coherence may help to explain at least some of the exceptional abilities shown by savants, where attention to detail is paramount. For example, Stephen Wiltshire's drawings seem to be built up from detail to the whole (not vice versa: Powell, 1999). However, this interpretation *wouldn't* apply to the artist Richard described by Hermelin *et al.* (1999: see Case Study 40.2, page 686).

The tendency to process at a local level will benefit when tasks require an analytical approach, and where global processing can be distracting (as in finding embedded figures: Shah & Frith, 1983). This may also account for the everyday observation that autistic individuals may locate fine detail or identify slight changes to familiar objects or layouts that go unnoticed by others (Powell, 1999). However, this style of thinking may not be unique to people with autism.

Impaired executive functioning

Executive functions refer to the ability to 'maintain an appropriate problem-solving set for the attainment of a future goal' (Ozonoff *et al.*, 1991) and include planning, impulse control, and working memory (WM: see Chapter 17). Autistic individuals may become distressed by changes in their immediate environment which interfere with their ritualised behaviours, they don't plan ahead well, and they often seem unable to anticipate the consequences of their actions.

Box 40.6 Executive functioning and the brain

- Executive functioning is believed to depend on intact *frontal lobes* (see Chapter 4). There's increasing evidence for poor performance on many 'frontal' tasks in autism (Frith, 1996).
- Rigidity and *perseveration* (ritualistic repetition of certain behaviours) are found both in patients with frontal lobe damage and individuals with autism, implying that autism may involve frontal lobe impairments. But patients with frontal lobe damage are strikingly *not* autistic (Frith, 1996).
- One possible explanation for these apparently inconsistent findings is that brain damage from birth and in later life produce very different behavioural pictures – even if the same brain area is involved. The later damage would be expected to have more *specific* consequences.

So, although an executive function deficit *alone* cannot account for the specific nature of autism (Lewis, 2003), it can potentially explain several features not tackled by ToM (Frith, 1996). Frith concludes by saying:

It seems unlikely that one single cognitive abnormality can be identified that would explain all the abnormalities present in autism. The existence of multiple deficits ... might help us understand why autism can exist in many different forms ranging from mild to severe. The explanation of autism at the cognitive level needs to be complemented by the explanation at the biological level ...

Treating autism

- *Biological approaches* include the use of the neuroleptic drug *haloperidol* and serotonin-reducing drugs such as *fenfluramine*. However, results have been disappointing and as with all powerful *psychoactive drugs*, are associated with side-effects (see Chapter 45).
- Other biological approaches derive from the observation that certain allergies produce behaviours similar to those seen in autism, such as headbanging and screaming. Consequently, *orthomolecular therapy*, in which autistic children are placed on low-carbohydrate diets, and megavitamin therapy, in which large daily doses of vitamin B6 are given, have been tried.
- *Behavioural approaches* include *behaviour modification*, which has been used to eliminate some aspects of autism such as self-mutilative behaviour. These behaviours, as with screaming, aren't unique to autism, and are actually more common in those with severe LDs. Typically, these approaches use *positive reinforcement* or *extinction*, although these can be time-consuming (Harris *et al.*, 1991).

For example, Simmons & Lovaas (1969) found that it took 1800 head bangs over an eight-day period before that behaviour was extinguished – by the withdrawal of social attention. Controversially, *punishment* (in the form of electric shock) has been used with autistic children, mainly for removing self-harming behaviour, and appears to be highly effective. As Lovaas (1977) states:

Seemingly independently of how badly the child is mutilating himself or how long he has been doing so, we can essentially remove the self-destructive behaviour within the first minute.

ASK YOURSELF...

- Try to formulate some arguments for and against the use of electric shock for self-mutilative behaviour in autistic (or other) children and adults.

Autistic children are clearly not transformed into 'normal' children by behavioural methods, and the behavioural changes that may be achieved in the therapeutic setting may not generalise to other settings. However, they may provide autistic children with enough adaptive behaviours to cope more effectively with the world. Perhaps even more importantly, such methods may make the children more socially acceptable and more 'rewarding' for other people. This, in turn, will provide the children themselves with more rewarding experiences and exchanges with others.

- *Cognitively based approaches* involve *structural therapy,* in which the environment is arranged so that the child will receive spontaneous physical and verbal stimulation in the form of play and games. By increasing the amount of stimulation, the therapy aims to make them more aware of themselves and their environment, and relate more to it.
- Other approaches aim to include the parents of autistic children in the treatment programmes (which recognises their role as potential agents of change), and teaching children sign language. This takes advantage of their sensitivity to touch and movement, and gets round the quite common problem of their failure to respond to spoken language (Webster *et al.*, 1973). Music may represent an alternative form of communication – and self-expression – as illustrated by the case of Hikari Kenzaburo (see Case Study 40.3, page 686).
- Current research is looking at developing new interventions in particular areas. One such study has been trying to teach ToM to children with autism.

KEY STUDY 40.3 Teaching ToM (Scott, 2004)

- One attempt to teach ToM uses a *metaphor* that autistic children can comprehend, because it works on the principles of a physical sequence of events and utilises equipment they understand (cameras and photographs).
- The children are given a false-belief task, but instead of using normal dolls or cartoons, they're trained using a plastic doll's head, 'John', which has a slit in the top. Photographs of the events can be posted into the slit.
- A photo is taken of John's 'thoughts' (e.g. the location of something he really likes, such as chocolate), the child posts it into his head, the item John likes is moved, and the child is asked 'Where will John look for his (chocolate)? Where does he think it is?'
- The children succeeded on the tasks with this training: they realised that 'John's' behaviour is driven by his thoughts, and not by reality (where the chocolate *actually* is). But they couldn't always generalise to new situations, and, of course, in real life we don't always know what someone else is thinking. However, this kind of methodology provides a starting point for training ToM and could help reduce the social problems experienced by people with autism (Scott, 2004).

LEARNING DIFFICULTIES (LDS)

LDs and learning disabilities, and mental impairment

'Learning difficulty' is defined by the Education Act 1993 as:

> A condition that exists if a child has significantly greater difficulty in learning than the majority of children of his age, or a disability which either prevents or hinders him from making use of educational facilities of a kind generally provided for children of his age in schools within the area of the local education authority.

While the term 'learning disability' isn't used in any relevant legislation (Lyon, 1995), it's the generally accepted term in service provision in the UK (e.g. by social workers). But education authorities, and the Code of Practice for Special Educational Needs, use the legally defined term 'learning difficulties' to refer to preschool and school-age children who, as adults, would be identified as having 'learning disabilities' (Dockrell *et al.*, 1999).

LDs (children)/learning disabilities (adults) cover what have variously been called 'mental handicap', 'mental subnormality' and 'mental retardation'. The last term is still commonly used in the USA, is used by the two major systems for classifying mental disorders, DSM-IV-TR (2000) and ICD-10 (1992: see Chapter 43), and is the internationally used term (Carpenter, 1997; Gelder *et al.*, 1999).

Another legally defined term is 'mental impairment'. According to the Mental Health Act (1983), mental impairment is:

> A state of arrested or incomplete development of mind which includes significant impairment of intelligence and social functioning.

Diagnosing LDs

People diagnosed with LDs don't all experience the same type or degree of problem. They come from all social-class and ethnic backgrounds, but black people with LDs experience two sorts of oppression at the same time (see Chapter 25). Assessment measures may be biased, either in terms of the materials used or the assessment situation itself. Many standard test procedures and equipment are based on white, middle-class values and experiences, producing an underestimation of an individual's level of competence (Chaudhury, 1988).

IQ is still the main criterion used to diagnose LDs. However, the extent of impairment in children's ability to adapt to the demands of society is crucial for considering the likelihood of their successful integration into mainstream school (Dockrell *et al.*, 1999). Also, a diagnosis of LD (or mental retardation) is made only if the individual is under 18 (Carpenter, 1997). A distinction is commonly made between LDs which have known *organic* (genetic or

brain-related) causes, and those which don't, and this distinction is associated with different degrees of difficulty (see Table 40.1).

Prevalence (the proportion of the whole population affected) has changed little since the 1930s, because people with LDs are living longer. However, the incidence (the number of *new* cases) of *severe* mental retardation has fallen by one-third. Half of that fall is attributable to improved antenatal and neonatal care (Gelder *et al.*, 1999).

Table 40.1 Different categories of mental retardation

Name	IQ range	Prevalence (proportion of the whole population which is retarded)	Description
Mild	50–70	3% (80% of all cases)	Adults can be expected to acquire some independence in most self-care/domestic activities, and earn money from unskilled work. Main difficulties will be in reading, writing, monetary skills, emotional and social immaturity, and inability to adapt readily to social expectations and external stressors.
Moderate	36–49	0.3% (12% of all cases)	Adults frequently have additional disabilities, such as epilepsy, and physical and sensory disabilities. Most need supervision with self-care.
Severe	20–35	0.04% (7% of all cases)	As above.
Profound	Below 20	0.05% (1% of all cases)	Adults usually need close supervision and care their whole life. Many can feed themselves with a spoon, most can understand and make simple statements and requests. Most have multiple disabilities.

(Based on Carpenter, 1997; Gelder *et al.*, 1999)

The causes of LDs

According to Carpenter (1997):

> ... because of the multiple stages in producing 'disability', it is usually a gross simplification to speak of one cause for the aetiology of a person's learning difficulty. Similarly, it is very difficult to predict accurately the degree of learning difficulty that will be produced by a specific organic cause.

People with *mild* LDs don't usually have clear aetiological diagnoses, that is, there's seldom an obvious, single cause. Most have family histories of low IQ, but it's unclear if this reflects a genetic influence, the effects of the environment, or the effects of undocumented specific causes. For example, it was traditionally assumed that mild LDs were caused by genetic and sociocultural factors. The discovery of *fragile X syndrome* (see Box 40.4, pages 692–693) and *foetal alcohol syndrome* (FAS: see Box 40.7) has suggested that (other) more specific causes will be discovered in time. However, it's rare for a child from a high socio-economic background to have either mild or severe LDs without some medical cause being apparent (Carpenter, 1997).

As Dockrell *et al.* (1999) say:

> The mild level of learning difficulty is viewed primarily as an academic dysfunction, or as a deficiency in learning ability with aetiology unknown, while severe learning difficulty (IQ below 50) is often viewed as physiologically caused handicap.

People with *severe or profound* LDs are more likely to have an identifiable *primary* cause, usually genetic. The most common known autosomal chromosomal abnormality responsible for intellectual impairment is Down's syndrome (see above). This occurs in one-third of people with an IQ below 50 (Carpenter, 1997). The most common well-documented single-gene recessive defect is *phenylketonuria* (PKU), which affects 12 in 1,000,000 people. This is routinely tested for at birth in the UK, and a special diet can prevent LDs from developing. But an appreciable minority still isn't put on the special diet within three weeks of birth (Carpenter, 1997).

Secondary causes include the following.

- *Hypothyroidism:* in its severe form, this used to be called 'cretinism'. One cause is cerebral palsy (see below), but early detection and administering thyroxine within the first three months of life will prevent intellectual impairments. But many affected children will also be deaf, which can impair intellectual development.
- *Cerebral palsy:* this can be *congenital* (present at birth), as in congenital *rubella* (German measles) but may also result from postnatal events. About one-third of full-term infants with cerebral palsy have severe LDs, and it's much more common in low-birthweight (premature) babies (but only 20 per cent of the latter have severe LDs).
- *Neural tube abnormalities: spina bifida* is one example, affecting 70–150 per 100,000 live births. Up to 10 per cent will have LDs, and almost all of these will be multiply handicapped.
- *Foetal alcohol syndrome* (FAS).

Box 40.7 Foetal alcohol syndrome (FAS)

- Children with FAS (first identified by Jones *et al.*, 1973) are typically smaller than normal and suffer from *microcephaly* (unusually small heads and brains).
- Such children often have heart defects, short noses and low nasal bridges. The eyes, too, have a distinctive appearance.
- FAS children are generally mildly retarded, though some may be moderately retarded and others of average intelligence. But in those of average intelligence, there are significant academic and attentional difficulties (Sue *et al.*, 1994).
- The syndrome is a consequence of the mother's excessive alcohol consumption during pregnancy. While there doesn't seem to be an agreed 'safe' level of maternal drinking during pregnancy, there appears to be a linear relationship between the amount of alcohol consumed and the risk of FAS. Binge drinking may be as dangerous as regular drinking.

A child with FAS

Specific learning difficulties: dyslexia

What is dyslexia?

ASK YOURSELF...

- What do you understand by the term?
- How do you think the term is commonly understood?

The terms 'specific learning difficulty' and *dyslexia* (literally 'non-reading') are often used interchangeably. People with dyslexia are of average intelligence, and have no visual or auditory impairments. *Acquired dyslexia* occurs in previously literate people following brain injury, while *developmental dyslexia* occurs in children as they get older. Most psychological theory and research are concerned with the latter.

Dyslexia (or 'congenital word blindness') became categorised as a LD in the 1981 Education Act, but it was first described in 1896 (in the *British Medical Journal:* Snowling, 1998). The case described 14-year-old Percy, who displayed many common characteristics, including:

- *dysphonetic spelling errors* (e.g. 'carefully' becomes 'calfuly')
- *substitutions of phonemes* (e.g. 'peg' becomes 'pag')
- *transpositions of letters* (e.g. 'Percy' becomes 'Precy').

Percy seemed to have *phonological dyslexia,* which affects letter–sound conversion. The individual cannot convert written words to their sounds directly or pronounce written words s/he hasn't seen before. For example, if asked to pick two words which rhyme from a list of 'rite', 'rit', and 'knight', the individual is more likely to select the first two – because they're *visually similar.*

Surface dyslexia affects whole word recognition. So, the individual can recognise a word only by sounding it out, rather than reading it by sight. Words which break standard pronunciation rules, such as 'broad', cannot be read correctly, and their pronunciation may be regularised ('brode'). *Deep dyslexia* affects reading for meaning. The individual is unable to pronounce aloud non-words, has difficulty with function words (sometimes substituting one for another), and often responds to real words with words of similar meaning (Coltheart *et al.*, 1983).

Diagnosing dyslexia

Children with dyslexia are usually contrasted with those who have reading difficulties in the context of more general learning problems (*reading backwardness*) (Rutter & Yule, 1975; Silva *et al.*, 1985). Many children are poor readers, but their underachievement can usually be attributed to below-average ability, emotional/behavioural disorders (such as attention-deficit hyperactivity disorder/ADHD), or environmental factors (such as school absence or sociocultural deprivation). Conversely, the reading and writing attainments of children with dyslexia are significantly below the level predicted based on their levels of general intelligence – despite normal functioning and adequate educational opportunity (Egan, 1998). Diagnosis of dyslexia is based on this discrepancy between expected and actual reading attainment (Snowling, 1998).

The incidence of dyslexia

Dyslexia has been reported in most countries with universal education, and in both European and non-European languages. It's often familial and occurs in all ability ranges and social-class groups. Allowing for differences in diagnostic criteria, it's estimated that about 4 per cent of school-age children are dyslexic (Egan, 1998). Snowling (1998) puts the figure at between 4 and 7 per cent. Early studies typically reported an excess of boys (four to one), but more recently the reported ratios have been much closer (Snowling, 1998).

Explaining dyslexia

According to Egan (1998), since reading isn't a 'natural' skill (unlike speech), it's unlikely to have its own specialised brain area controlling it. Models of word-recognition suggest that reading involves two letter–brain routes: visual and phonemic (see Chapter 19).

Visual perceptual deficits

The visual route is used to match letter sequences to particular words stored in memory. Some fairly common visual errors include:

- reading words/letters in a back-to-front way (e.g. 'saw'/'was'; 'b'/'d')
- contracting words (e.g. 'tenable'/'table')
- reading sentences in the wrong order (e.g. 'he was going out'/'he was out going').

Dyslexics make these visual errors only on perceptual tasks involving symbolic material (i.e. word-related), and their visual errors are also similar to those made by young children learning to read. These data suggest that dyslexics' visual errors are caused by their reading disability – not vice versa. However, the case of A.S. casts some doubt on this conclusion.

CASE STUDY 40.4 A.S. (Wydell and Butterworth, in Uhlig, 1996)

- A.S. is a 17-year-old boy living in Japan with his English mother and Australian father. His first language is English, which is used exclusively at home. But at age six, he went to a Japanese-speaking school.
- A.S. has no difficulty with Japanese, and can use university textbooks. His English, though, is behind his classmates', and at age 13 it was confirmed that he was dyslexic in English but not in Japanese.
- Japanese has two written forms – *kanji* and *kana*. Kanji symbols have meaning but no phonetic values. If A.S.'s dyslexia were the result of a visual processing problem, he should have more difficulties with kanji than English – but he clearly doesn't.
- He appears to suffer from a form of dyslexia that could be unique to English. The many pronunciation and spelling irregularities in English apparently confuse the method by which A.S. assigns sounds to letters.

Phonological deficits

The phonemic route is used to match letters and combinations of letters with the spoken form of words. Although skilled readers rarely use this route, it's important in learning to read. Young children first learn to associate particular patterns of letters with pictures or spoken words ('whole word' reading), but this doesn't allow them to 'decode' new words. So they need to identify the individual sounds (phonemes) in words and blend them to produce words (e.g. 'k-ah-tuh' ... 'k-ahtuh' ... 'kat' ... 'cat': Egan, 1998).

Dyslexics have extreme difficulty with this process. Words appear to be indivisible and they seem to be 'arrested' at the 'whole word' reading stage (Frith, 1985). For example, when M.B. (a 12-year-old, with an IQ of 116 but a reading age of eight years, two months) was presented with unfamiliar words, he replaced them either with real words that looked like the target (e.g. 'smoulder'/'soldier') or with nonsense words (e.g. 'saucer'/'shaller') (Egan, 1998).

The ability to segment, 'sound out' or blend words are all functions of *phonological awareness:* the ability to reflect on or mentally process the sound structure of spoken words. According to the *core phonological deficit* (CPD) model of dyslexia (Stanovich, 1986; Stanovich & Siegel, 1994), dyslexia essentially involves very limited phonological awareness.

Box 40.8 Dyslexia and the brain

- Some people with developmental dyslexia show atypical asymmetry in the *plenum temporale* (in Wernicke's area: see Chapter 4). This is evidently directly associated with phonological coding deficits. However, these neurological problems are also found in children who are generally poor readers.
- Studies using imaging techniques (such as PET: see Chapter 4) have found reduced activity in the *insula* of dyslexic participants compared with non-dyslexic controls on phonological tasks (but not on visual-processing tasks).
- The insula is located between Wernicke's and Broca's areas, and is known to be involved in the transmission of language. It may play a role in translating between spoken inputs and speech production (Snowling, 1998).

Is dyslexia really a distinct reading difficulty?

Just as some of the brain abnormalities implicated in dyslexia may not be unique to dyslexics, so the underlying phonological deficits also occur in 'plain' poor readers (age-matched controls whose poor reading ages can be accounted for by their lower IQs). In other words, phonological deficits cannot differentiate dyslexics from other poor readers. This and other evidence makes it increasingly difficult to justify studying and treating developmental dyslexia as if it were entirely distinct from the poor reading shown by children disadvantaged by low general intelligence, inadequate home preparation, or poor teaching (Coltheart and Jackson, 1998; Snowling, 1998).

Does dyslexia involve a mainly phonological deficit?

There's also evidence to suggest that the primary cause of reading difficulties in developmental dyslexia has nothing to do with phonology at all. For example, Castles & Coltheart (1993) found that some children's difficulties were *orthographic,* that is, they failed to develop an adequately large *sight vocabulary* (while their ability to map from letters to sounds was normal). This is *surface dyslexia.* Where this second ability is also impaired, the impairment is called *phonological dyslexia.* These represent two distinct patterns of developmental reading difficulty (Coltheart & Jackson, 1998).

Other researchers (e.g. Stein & Fowler, 1985) believe that in at least some children with developmental dyslexia, the central difficulty is *oculomotor,* that is, the reading difficulty is caused by poor control of eye movements.

Some concluding comments about dyslexia

According to Coltheart & Jackson (1998), the *same proximal cause* (some abnormality in the information-processing system the child is using, such as weak phonological awareness) can itself be the product of *different distal causes* (the reason for this system being abnormal, e.g. congenital, environmental, educational). Coltheart and Jackson believe that effective treatment interventions will be defined largely (although not exclusively) by the proximal causes. This approach treats children as individuals, producing individual profiles which are then compared with age-related norms. When such an approach is adopted:

The term 'dyslexia' has no role to play ...

CHAPTER SUMMARY

- **Gifted children** tend to be **precocious**, make discoveries on their own, have an obsessive interest in their domain of giftedness, and have unusually good **metacognitive skills**.
- Cases like those of Sufiah Yusof and Ruth Lawrence illustrate the kinds of social and emotional problems gifted children are prone to.
- Terman's study of giftedness also created the myth that these children are **globally** gifted. In fact, the **unevenness** of gifted children's abilities is quite common and **savants** such as Stephen Wiltshire illustrate the unevenness of abilities in an extreme form.
- Both savants and non-savant gifted children appear to have **atypical brain organisation**. This may account for the '**pathology of superiority**' and may be caused by '**testosterone poisoning**'.
- The belief that giftedness is hardwired in the infant brain is consistent with the '**talent account**'. But critics argue that talents are mythical, that temperamental and personality qualities, rather than cognitive ones, are what set geniuses apart from the rest of us, and that practice from an early age is the crucial environmental influence.
- **Autism** has been defined in terms of the **triad of impairments**: **social relationships**, **language/communication** and **stereotyped/repetitive behaviour**. There's a **wide spectrum of autistic disorders**, which includes **Asperger's syndrome**.
- An early, unsuccessful, attempt to explain autism was the '**refrigerator-parenting**' hypothesis. Many researchers believe that there's compelling evidence for a strong **genetic** component underlying autism, based on studies of siblings of autistic individuals and of identical/non-identical twins.
- The strongest evidence for autistic children's lack of a **theory of mind** (ToM) and **mind-blindness** is their consistent failure on **false belief tasks**. By comparison, Down's syndrome and normal children reliably pass them.
- However, ToM cannot explain all aspects of autism. Two alternative, complementary, cognitive explanations are **weak central coherence** and **impaired executive functioning**.
- Another complementary explanation is Baron-Cohen's **empathising-systemising** (E-S) **theory**, according to which the autistic individual has an **extreme male brain**.
- Autism is treated by **drugs** and other biological approaches, **behaviour modification**, and more cognitively based approaches, such as **structural therapy** and **training on false-belief tasks**.
- **Learning difficulty** (LD) is a legally defined term, synonymous with **learning disability**, and the internationally used term **mental retardation**. **Mental impairment** is another legally defined term that overlaps with learning difficulty.
- LDs are defined primarily in terms of IQ, but the ability to adapt to society's demands (children) and to be self-sufficient (adults) are also taken into account. **Mental retardation** is usually subdivided into **mild**, **moderate**, **severe** and **profound**.
- **Primary** (organic: genetic or brain-related) **causes**, such as **Down's** and **fragile X syndromes**, are usually associated with severe and profound LDs. **Secondary** (non-genetic) **causes** include FAS and sociocultural and other environmental factors.
- **Dyslexia** (or **specific LD**) may be **developmental** or **acquired**, **surface** or **deep**. It's distinguished from reading backwardness, in which low reading attainment is predicted from more general learning problems.
- The most influential account of dyslexia has been the **core phonological deficit** (CPD) **model**, according to which dyslexics have very limited **phonological awareness**.
- However, this deficit (and related brain abnormalities) may not be unique to dyslexia. Also, the core deficit may sometimes be **orthographic** or **oculomotor**. It's important to distinguish between **proximal** and **distal** causes of dyslexia.

Links with other topics/chapters

- Both exceptionally high achievers (such as Sufiah Yusof and Ruth Lawrence) and Down's syndrome children are *statistically abnormal,* but their behaviours and abilities are clearly very different, as are the *valuations* placed on them by society (Chapter 43).
- Metacognition is an important feature of the *information-processing approach* to understanding *cognitive development* (Chapter 34).

- The left-hemisphere hypothesis explanation of savant syndrome rests on the assumption that the two hemispheres really are different in the kinds of abilities they control (*cerebral lateralisation/lateralisation of brain function*). This is by no means uncontroversial (Chapter 4).
- According to Treffert & Wallace (2004), savant syndrome provides a unique window into the brain regarding *general vs multiple forms of intelligence* (Chapter 41), *plasticity, compensation* and *repair* (Chapter 4). The latter are vital in understanding and treating conditions such as Alzheimer's disease (Chapter 39).
- To say that talents cannot be manufactured is another way of claiming that they develop through *maturation* (Chapter 50).
- ICD-10 (International Classification of Diseases, 10th edition, published by the World Health Organization, 1992) and DSM-IV-TR (Diagnostic and Statistical Manual of Mental Disorders, 4th edition, Text Revision, published by the American Psychiatric Association, 2000) are the two most widely used systems for *classifying* and *diagnosing* mental disorders (Chapter 43).
- Autism is often described as the most severe of all child psychiatric disorders, because, unlike other disorders, people with autism seem to be virtually cut off from other people ('in a world of their own'). This is why it's sometimes categorised as a *psychosis,* implying that it's unlike anything in the normal range of experience (Baron-Cohen, 1995a) (Chapter 43).
- Twin studies (comparing DZs with MZs, the latter both reared together and reared separately) is one of the major methods for assessing the influence of genetic factors involved in *intelligence differences* (Chapter 41), *schizophrenia and other mental disorders* (Chapter 44), and so is crucial for the *nature–nurture debate* as a whole (Chapter 50).
- Baron-Cohen's E-S theory is relevant to understanding *psychological sex differences* (Chapter 36).
- All the treatment approaches used with autistic individuals are also used with adults with a wide range of mental disorders (Chapter 45).
- Phenylketonuria (PKU) is often discussed in the context of the *nature–nurture debate* to illustrate how genes don't inevitably produce particular behavioural effects (Chapter 50).

INTELLIGENCE

INTRODUCTION AND OVERVIEW

The concept of intelligence is one of the most elusive in the whole of psychology. Perhaps nowhere else in psychology does so much of the research and theory attempt to define the concept under investigation.

But intelligence isn't just of academic interest. The intelligence test (in one form or another) has impinged on the lives of most of us, whether in the context of educational or occupational selection, or even selection for Mensa, the high-IQ society.

How intelligence is conceptualised varies enormously. *Biological definitions* see intelligence as related to *adaptation to the environment*. For Piaget (1950), intelligence is:

> ... essentially a system of living and acting operations, i.e. a state of balance or equilibrium achieved by the person when he is able to deal adequately with the data before him. But it is not a static state, it is dynamic in that it continually adapts itself to new environmental stimuli.

Piaget is interested in the *qualitative* aspects of intelligence, that is, the nature of intelligence itself.

By contrast, the *psychometric* ('mental measurement') approach is concerned with measuring *individual differences* in intelligence, through the use of intelligence (IQ) tests, and so emphasises the *quantitative* aspects of intelligence. It is this approach, associated with psychologists such as Spearman, Burt, Vernon, Thurstone, and Guilford, that has predominated until fairly recently. Important alternatives to the psychometric approach are Sternberg's *information-processing approach* and Gardner's *theory of multiple intelligences*.

The near-obsession of western society with measuring and categorising people is emotionally charged and politically sensitive, especially in relation to the 'race and IQ' debate. This is one form of the nature–nurture/heredity–environment debate, which has become associated with extremes of political viewpoints. It highlights the impossibility of completely divorcing the social from the scientific functions of psychology (see Chapter 3).

DEFINING INTELLIGENCE

ASK YOURSELF...

- How would you define intelligence?

Most definitions reflect the *psychometric approach*. As we saw in the *Introduction and overview*, this is concerned with the measurement of intelligence in order to compare 'how much' of it different individuals possess (see Table 41.1).

ASK YOURSELF...

- What similarities and differences are there between the different definitions in Table 41.1?

The definitions of Terman, Burt and Vernon all stress the purely cognitive/intellectual aspects of the concept, while those of Binet and Wechsler are much broader and perhaps closer to common-sense understanding. But Heim objects to the use of intelligence as a noun, because it smacks of an 'isolable entity or thing'. This is contrary to her belief that intelligence should be regarded as part of *personality as a whole*. Consequently, she prefers to talk about 'intelligent activity' rather than 'intelligence'.

Table 41.1 Some definitions of intelligence

'It seems to us that in intelligence there is a fundamental faculty, the impairment of which is of the utmost importance for practical life. This faculty is called judgement, otherwise called good sense, practical sense, initiative, the faculty of adapting one's self to circumstances. To judge well, to comprehend well, to reason well ...' (Binet, 1905)
'An individual is intelligent in proportion as he is able to carry on abstract thinking.' (Terman, 1921)
'... innate, general, cognitive ability' (Burt, 1955)
'... the aggregate of the global capacity to act purposefully, think rationally, to deal effectively with the environment' (Wechsler, 1944)
'... the effective all-round cognitive abilities to comprehend, to grasp relations and reason' (Vernon, 1969)
'Intelligent activity consists in grasping the essentials in a situation and responding appropriately to them.' (Heim, 1970)
'... the ability to deal with cognitive complexity' (Gottfredson, 1998)

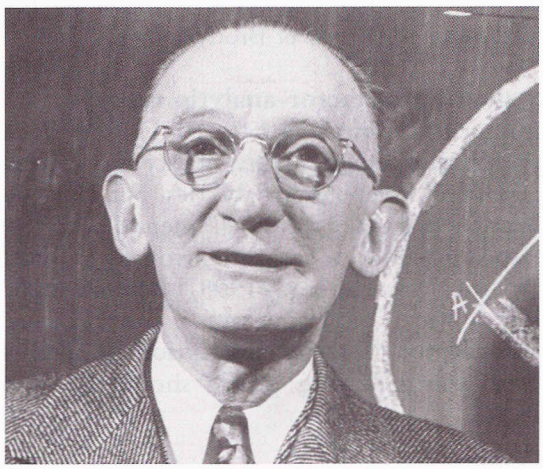
Other definitions

An *operational definition* defines intelligence in terms of tests designed to measure it, that is, 'Intelligence is what intelligence tests measure' (Boring, 1923). But this begs the question as to what intelligence tests measure and is *circular* (the concept being defined is part of the definition itself). Miles (1967) argues that if we substitute the names of particular tests, then we can break into the circle, but Heim points out that this merely decreases the circumference of the circle!

Like Heim, Ryle (1949) believes that 'intelligence' doesn't denote an entity or an engine inside us causing us to act in particular ways. Rather, any action can be performed more or less intelligently, so it should be used as an adjective and not as a noun.

THEORIES OF INTELLIGENCE

Psychometric (factor-analytic) theories



Psychometric theories are based upon analysis of scores of large numbers of individuals on various intelligence tests using a statistical technique called *factor analysis* (FA).

Box 41.1 Factor analysis (FA)

- This involves correlating the scores of a large sample of participants to determine whether scores on certain tests are related to scores on certain other tests (whether some, or any, of the tests have something in common).
- The basic assumption is that the more similar the scores on two or more tests (the higher the *correlation*), the more likely it is that these tests are tapping the same basic ability (or *factor*).
- For example, if we find that people's scores on tests A, B, C, D and E are highly correlated (if they score highly on

one they tend to score highly on the others), then it could be inferred that (a) all five tests are measuring the same ability, and (b) individuals differ according to how much or how little of that particular ability they have.
- But if there's very little relationship between scores on the five tests, then each test may be measuring a distinct ability, and when comparing individuals we'd have to look at each ability separately.

The two hypothetical outcomes in Box 41.1 correspond roughly to two theories of intelligence: (a) the 'London line' is associated with Spearman (1904, 1967), Burt (1949, 1955), and Vernon (1950); (b) the mainly American approach of Thurstone (1938) and Guilford (1959).

L.L. Thurstone (1887–1955)

Spearman's two-factor theory

Spearman factor-analysed the results of children's performance on various tests, and found that many tests were moderately positively correlated. He concluded that every intellectual activity involves both a general factor (*g* or general intelligence) and a specific factor (*s*), and differences between individuals are largely attributable to differences in their *g*. (*g* is, in fact, an abbreviation for *neogenesis,* the ability to 'educe relations', as in a common kind of test item which asks 'A is to Y as B is to ?'). *g* accounts for why people who perform well using one mental ability also tend to perform well in others, and is entirely innate.

Spearman himself believed that he'd discovered the elusive entity, the innate essence of intelligence, that would make psychology a true science. As Gould (1981) puts it:

> Spearman's *g* would be the philosopher's stone of psychology, its hard, quantifiable 'thing' – a fundamental particle that would pave the way for an exact science as firm and as basic as physics ...

Although this proved to be a rather exaggerated claim, Guilford (1936, in Gould, 1981) believed that:

> No single event in the history of mental testing has proved to be of such momentous importance as Spearman's proposal of his famous two-factor theory.

Burt and Vernon's hierarchical model

Burt (who was a student of Spearman) agreed that there's a *g* factor common to all tests, but also thought that the two-factor model was too simple. He and Vernon elaborated and extended Spearman's model by identifying a series of *group factors* (major and minor) in between *g* and *s* factors (see Figure 41.1). *g* is what *all* tests measure, the *major group factors* (v:ed and k:m) are what *some* tests measure (some to a greater extent than others), the *minor group factors* are what *particular* tests measure whenever they're given, while *specific factors* are what particular tests measure on specific occasions (Vernon, 1971).

An important *educational* implication of this model is that, given the dominance of *g* in the hierarchy, each child can be ranked on a single scale of (innate) intelligence. *g* can be measured early in life, and children sorted according to their intellectual promise. (This is the thinking behind the eleven-plus examination: see Box 41.3, pages 713–714.)

Thurstone's primary mental abilities

Using 14-year-olds and college students as his participants, Thurstone (1935, 1938, 1947) found that not all mental tests correlate equally. Rather, they appear to form

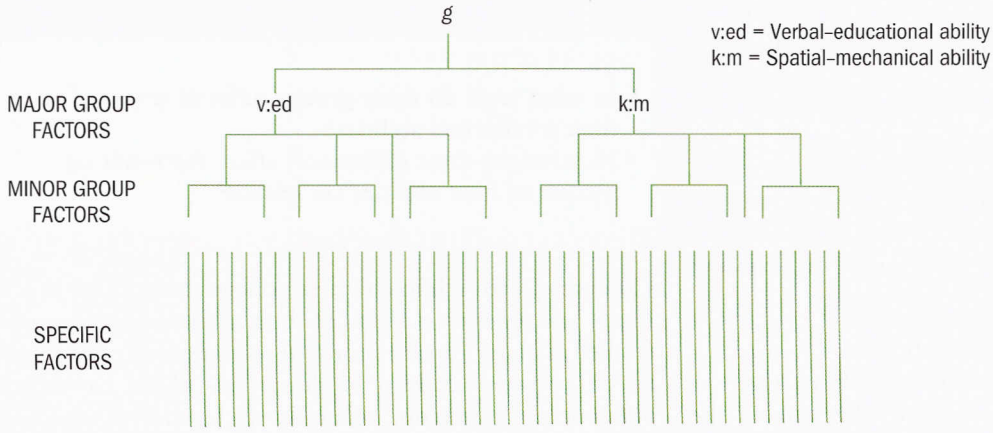


Figure 41.1 The hierarchical model of intelligence (after Vernon, 1950)

seven distinct factors or groupings, which he called *primary mental abilities* (PMAs), namely:

- *spatial* (S) – the ability to recognise spatial relationships
- *perceptual speed* (P) – the quick and accurate detection of visual detail
- *numerical reasoning* (N) – the ability to perform arithmetical operations quickly and accurately
- *verbal meaning* (V) – understanding the meaning of words and verbal concepts
- *word fluency* (W) – speed in recognising single and isolated words
- *memory* (M) – the ability to recall a list of words, numbers or other material
- *inductive reasoning* (I) – the ability to generate a rule or relationship that describes a set of observations.

Thurstone sometimes referred to these mental abilities as 'mental faculties' or 'the vectors of mind' (the title of his 1935 book). He saw *g* as a grand average of positive correlations for a particular battery of tests. This means that *g* can change according to the particular battery of tests used, and so it:

> ... has no fundamental psychological significance beyond the arbitrary collection of tests that anyone happens to put together ... We cannot be interested in a general factor which is only the average of any random collection of tests ... (Thurstone, 1940, in Gould, 1981)

So the PMAs are independent and uncorrelated. They correspond to the group factors in the hierarchical model, but there's no general factor to which they're all related. As there's no general ability, the overall ranking of pupils is inappropriate: some children will be good at some things, others at other things. He advocated the use of individual profiles of all PMAs. However, Thurstone (1947) later admitted that *g does* seem to be involved in all PMAs (having carried out a 'second-order' factor analysis on the results of the first: see Chapter 42).

Jensen (1980), a major advocate of the view that intelligence differences are largely genetic, believes that this change of mind by Thurstone proves that Spearman and Burt were right all along. Jensen is a 'pure Spearman-ian' (Gould, 1981), who claims that:

> To the extent that a test orders individuals on *g*, it can be said to be a test of intelligence.

However, Gould (1981) argues that *g* was still of secondary importance to the PMAs. Even after admitting a second-order *g*, Thurstone continued to contrast himself with the 'London line'.

Guilford's 'structure of intellect' model

This represents the most extreme alternative to Spearman's two-factor theory, and totally rejects the notion of a general intelligence factor. Guilford first classified a cognitive task along three major dimensions:

1. *content* (what must the participant think about?)
2. *operations* (what kind of thinking is the participant being asked to perform?)
3. *products* (what kind of answer is required?).

He identified five kinds of content, five kinds of operation, and six kinds of product which, multiplied together, yield a total of 150 distinct mental abilities (see Figure 41.2, see page 713). Guilford set out to construct tests to measure each of the 150 abilities, and tests have been devised to assess more than 70 (Shaffer, 1985). However, people's scores are often correlated, suggesting that the number of basic mental abilities is much smaller than Guilford assumed (Brody & Brody, 1976).

An evaluation of factor-analytic models

According to Vernon (1950, 1971), intelligence is neither a single general mental ability nor a number of more specific, independent abilities, but *both*. General intelligence plays a part in all mental activities, but more specific abilities are also involved in producing performance. Sternberg (1995) believes that this combined, hierarchical approach is probably the most widely accepted factorial description of intelligence. However, the following points should be borne in mind:

- there's more than one way of factor-analysing a set of data, and there's no 'best' way. Thurstone originally used a form of factor analysis (FA) which gives a 'simple structure' solution in contrast to the 'principal component' solutions resulting from Spearman's and Burt's analyses. Shackleton & Fletcher (1984) say that these two alternatives are mathematically equivalent, and the same data from the same sample can produce a number of different patterns of factors depending on which alternative is used
- Thurstone and Guilford used mainly college students, while Spearman, Burt, and Vernon used mainly schoolchildren.

ASK YOURSELF...

- In what ways do these groups differ in terms of their intellectual abilities?
- How might these differences affect the resulting picture of how abilities are related?

Compared with schoolchildren, college students are much more *homogeneous* in terms of their all-round intelligence (as well as being a much more *self-selected* group). So, differences between college students are likely to reflect differences in certain, relatively independent, abilities,

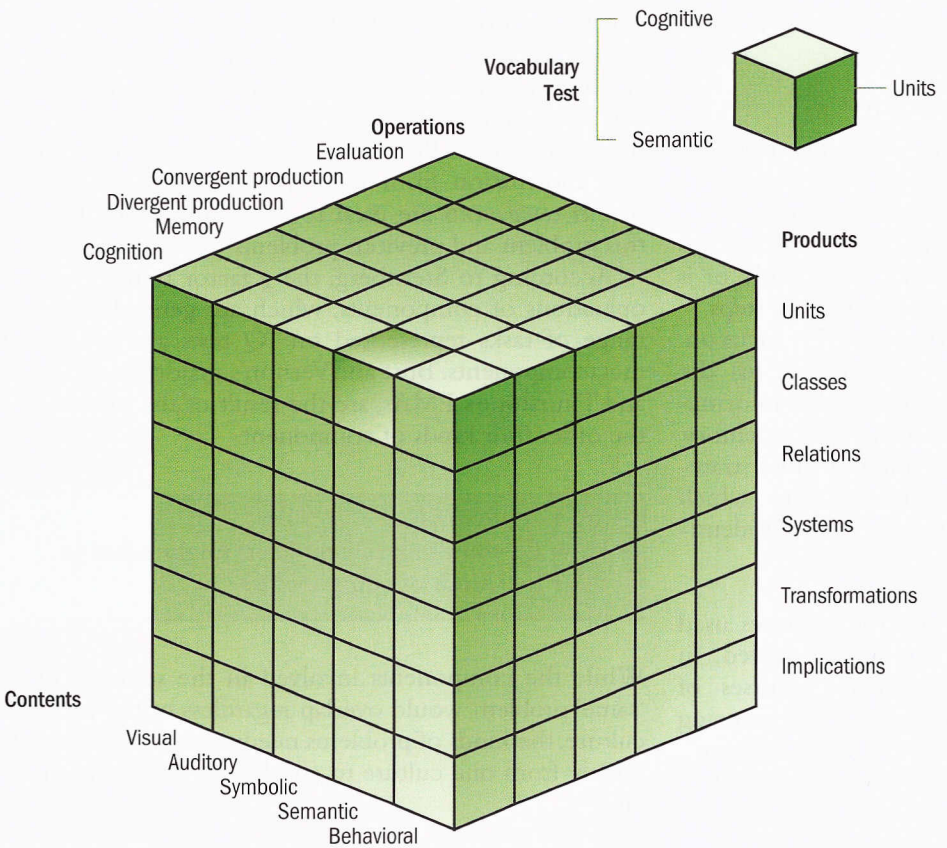

Figure 41.2 Guilford's (1967, 1982) structure of intellect model. (From Zimbardo, P. G., (1992) *Psychology and Life,* 13th ed. New York, Harper Collins Publishers. (Originally, Guilford identified 120 abilities, but he later distinguished between visual and auditory content (previously included under 'figural') giving $5 \times 5 \times 6 = 150$)

while differences between schoolchildren are likely to reflect more global, all-round ability.

- FA produces a cluster of intercorrelations between different tests and sub-tests – it's then up to the researcher to scan these patterns of intercorrelations and to label them. As Radford (1980) says, factors don't come 'ready-labelled', and the labels that are attached to the factors are only 'best guesses' about the psychological meaning of the factors – they may or may not reflect 'psychological reality'. In other words, clusters of intercorrelations are meaningless until they're given an interpretation by a psychologist
- once a factor has been labelled (e.g. 'verbal ability'), there's the danger of believing that it exists in some objective way (*reification*). But in reality, a factor is merely a statistic (or 'mathematical abstraction': Gould, 1981). As Gillham (1978) puts it:

> Factors, like human beings, are born with no name although there is usually one waiting for them, which may not fit their character very well. But as with their human counterparts they soon become assimilated to their name ...
>
> Human beings, however, have the advantage over factors in that their meaning does not reside just in their name. Factors, like correlation coefficients, have no intrinsic psychological significance: meaning is ascribed to them by a psychologist with his preferences and presuppositions ...

Fluid and crystallised intelligence

Working within the FA approach, Cattell (1963) and Horn & Cattell (1967, 1982) have proposed a model which can to some degree reconcile the different models discussed above. They argue that *g* can be subdivided into two major dimensions – *fluid* and *crystallised intelligence.*

- *Fluid intelligence* (*gf*) is the ability to solve abstract relational problems of the sort that aren't taught, and which are relatively free of cultural influences. It increases gradually throughout childhood and adolescence as the nervous system matures, then levels off during young adulthood, and after that begins a steady decline
- *Crystallised intelligence* (*gc*) increases throughout the lifespan, and is primarily a reflection of one's cumulative learning experience. It involves understanding

relations or solving problems which depend on knowledge acquired as a result of schooling and other life experiences (e.g. general knowledge, word comprehension and numerical abilities).

The information-processing approach

According to Fishbein (1984), the *information-processing approach* sees intelligence as the steps or processes people go through in solving problems. One person may be more intelligent than another, because s/he moves through the same steps more quickly or efficiently, or is more familiar with the required problem-solving steps.

Advocates of this view (e.g. Sternberg, 1979) focus on: (i) how information is internally represented; (ii) the kinds of strategies people use in processing that information; (iii) the nature of the components (e.g. memory, inference, comparison) used in carrying out those strategies; and (iv) how decisions are made as to which strategies to use. Regarding (iii), Sternberg (1987) identifies five major kinds of components:

1. *metacomponents* – higher-order control processes used in planning how a problem should be solved, in making decisions regarding alternative courses of action during problem-solving, and in monitoring one's progress during the course of problem solution
2. *performance components* – processes used in the actual execution of a problem-solving strategy
3. *acquisition components* – processes used in learning (acquisition of knowledge)
4. *retention components* – processes used in remembering (retrieval of previously acquired information)
5. *transfer components* – processes used in generalising (transfer of knowledge from one task or task context to another).

ASK YOURSELF...

- How might these five kinds of components be applied in the solution to the problem presented in Box 41.2?

Box 41.2

- Mrs Smith decided to impress Mrs Jones.
- She went to a costume jewellery shop and bought three imitation diamonds of equal value.
- She received £4 in change from the £10 note she gave the assistant. (But as Mrs Smith was receiving her change, Mrs Jones walked into the shop!)
- How much did each imitation diamond cost?

Metacomponents would be used in setting up the equations for solving the problem (e.g. in deciding that the problem can be solved by subtracting £4 from £10 and dividing the difference by three). They must also decide what information is relevant and what isn't. *Performance components* would be used in the actual solution of these equations to obtain first £6 as the price of the imitation diamonds and, then, £2 as the price of each item. *Acquisition components* were used in the problem-solver's past to learn how to set up the equation, how to subtract, divide and so on. *Retention components* are used to retrieve this information from memory when it's needed, and *transfer components* are used to draw an analogy between this problem and previous problems of a similar kind.

According to Sternberg, the *g* factor results from the operations of components, which are general across the range of tasks represented on IQ tests and are mainly metacomponents. Burt and Vernon's major group factors, and Thurstone's PMAs, are the result of the operation of the other four kinds of component.

ASK YOURSELF...

- How do you think *cultural factors* might relate to these five kinds of components?

While the components involved in the solution of the 'same' problem would overlap regardless of the particular culture, the kinds of problems needing solution will differ widely from one culture to another. As Sternberg (1987) says:

> ... the kinds of persons who are considered intelligent may vary widely from one culture to another, as a function of the components that are important for adaptation to the requirements of living in the various cultures.

Cultural context is central to Sternberg's contextual subtheory (see below), and the cultural nature of intelligence is discussed below (see page 719).

Information-processing theories are intended to be *universal* (like Piaget's), and at the same time to explain *individual differences* (like factor-analytic theories). As Fishbein (1984) puts it, they see intelligence as neither an 'it' (for example *g*) nor a 'them' (for example, PMAs), but as everything the mind does in processing information.

Sternberg's triarchic theory

Sternberg's (1985, 1988a) *triarchic theory* incorporates the components involved in information-processing, but is far broader. It comprises three *subtheories* which attempt to explain, in an integrative way, the relationship between:

- intelligence and the individual's *internal* world – that is, the mental mechanisms which underlie intelligent behaviour (the *componential subtheory*)
- intelligence and the individual's *external* world – that is, how these mechanisms are used in everyday life to attain an intelligent fit with the environment (the *contextual sub-theory*)

- intelligence and experience – that is, 'the mediating role of one's passage through life between the internal and external worlds of the individual' (Sternberg, 1990) (the *experiential subtheory*).

Componential subtheory

One of the most interesting classes of performance components are those found in *inductive reasoning,* the kind of thinking required in series completion tasks and analogies (e.g. 'A is to B as Y is to ?'). Sternberg (1990) believes that identifying these performance components can provide insight into the nature of *g.* However:

> ... there is more to intelligence than a set of information-processing components. One could scarcely understand all of what it is that makes one person more intelligent than another by understanding the components of processing on, say, an intelligence test ...

Contextual subtheory

Intelligent thought isn't aimless or random mental activity, but is directed towards one or more of three behavioural goals: *adaptation* to an environment, *shaping* of an environment, and *selection* of an environment. Regarding adaptation, Sternberg (1990) argues that what is intelligent in one culture may be considered unintelligent in another:

> To understand intelligence, one must understand it ... in terms of how thought is intellectually translated into action in a variety of different contextual settings ...

Shaping may represent the essence of intelligent thought and behaviour:

> Perhaps it is this skill that has enabled human kind to reach its current level of scientific, technological, and cultural advancement ... In science, the greatest scientists are those who set the paradigms (shaping), rather than those who merely follow them (adaptation) ...

Experiential subtheory

Intelligence is best measured at those regions of the experiential continuum that involve tasks or situations that are either relatively novel, on the one hand, or in the process of becoming automatised, on the other. To test how far children's understanding extends, you might give them problems which are just at the limits of their current understanding (this is similar to Vygotsky's *zone of proximal development:* see Chapter 34). Several sources of evidence suggest that the ability to deal with relative novelty is a good way of measuring intelligence.

ASK YOURSELF...

- In terms of *attention* theory and research, why is the ability to *automatise* so important? (See Chapter 13.)

The ability to *automatise* information-processing (e.g. as shown by a skilled reader: see Chapter 40) makes more resources available for dealing with novelty.

According to Bee (1989), standard IQ tests have omitted many of the kinds of abilities included under the contextual and experiential subtheories. In the world outside school, these may be required at least as much as those included under the componential subtheory. Clearly, traditional IQ tests don't measure all significant aspects of intellectual skill (see below, pages 713–717).

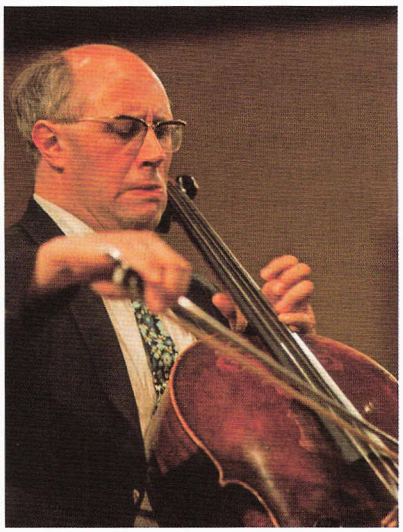
Gardner's theory of multiple intelligences

Gardner's (1983) *theory of multiple intelligences* (MI theory) is based on three fundamental principles:

1. Intelligence isn't a single, unitary thing but a collection of multiple intelligences, each one a *system* in its own right (as opposed to merely separate aspects of a larger system, i.e. 'intelligence').
2. Each intelligence is independent of all the others.
3. The intelligences interact, otherwise nothing could be achieved.

MI theory also makes two strong claims:

1. All humans possess all these intelligences, and collectively they can be considered a cognitive definition of *homo sapiens.*
2. Just as we all look different and have unique personalities and temperaments, so we also have different profiles of intelligences. No two individuals, not even identical twins, have exactly the same mix of intelligences, with the same strengths and weaknesses (see Chapter 42).



Gardner (1998) defines an intelligence as:

> ... a psychobiological potential to solve problems or fashion products that are valued in at least one cultural context.

Entire cultures may encourage the development of one or other intelligence. For example, the seafaring Puluwat of the Caroline Islands (in the South Pacific) cultivate spatial intelligence and excel at navigation. The Manus children of New Guinea learn the canoeing and swimming skills that elude the vast majority of western children (Gardner, 1998).

Gardner (1983) originally identified seven intelligences, and added an eighth, *naturalistic* (or 'the naturalist'), in 1995. Darwin is a good example. Gardner is currently considering the possibility of a ninth – *existential* intelligence, which captures the human tendency to raise and ponder fundamental questions about existence, life, death, and so on (e.g. the existential philosopher, Kierkegaard) (Gardner, 1998).

Gardner identifies eight different criteria for distinguishing an independent intelligence, including the following:

Musical intelligence in action

These boys from Papua New Guinea display how intelligence can be defined in terms of adaptations to the cultural environment

- *potential isolation by brain damage:* each intelligence resides in a separate region of the brain, so that a given intelligence should be isolable by studying brain-damaged patients. For example, naturalistic intelligence is based on evidence that certain parts of the temporal lobe are dedicated to naming and the recognition of natural things, while others are attuned to human-made objects. Brain-damaged people sometimes lose the capacity to identify living things, but can still name inanimate objects (Gardner, 1998: see Chapter 4)

Table 41.2 Gardner's eight intelligences

Linguistic: Includes skills involved in reading, writing, listening and talking
Logical–mathematical: Involved in numerical computation, deriving proofs, solving logical puzzles, and most scientific thinking
Spatial: Used in marine navigation, piloting a plane, driving a car, working out how to get from A to B, figuring out one's orientation in space. Also important in the visual arts, playing chess, and recognising faces and scenes
Musical: Includes singing, playing an instrument, conducting, composing and, to some extent, musical appreciation
Bodily–kinaesthetic: Involves the use of one's whole body or parts of it, to solve problems, construct products and displays. Used in dance, athletics, acting and surgery
Interpersonal: Includes understanding and acting upon one's understanding of others – noticing differences between people, reading their moods, temperaments, intentions, and so on. Especially important in politics, sales, psychotherapy and teaching
Intrapersonal: Self-understanding – symbolised in the world of dreams
Naturalistic: Permits the recognition and categorisation of natural objects (as in biology, zoology etc.)

- an identifiable *core operation or set of operations*
- support from *psychometric findings* (patterns of intercorrelations, based on FA: see Box 41.1)
- the existence of *idiots savants, prodigies,* and other *exceptional individuals* (see Chapter 40).

ASK YOURSELF...

- Explain how savant abilities suggest the existence of separate intelligences.

According to Gardner (1998), critics of MI theory are nervous about moving away from standardised tests and adopting a set of criteria that is less quantifiable. Many prefer to talk about musical or bodily-kinaesthetic *talents* rather than intelligences:

> Such a narrow definition, however, devalues these capacities, so that orchestra conductors and dancers are talented but not smart. In my view, it would be all right to call those abilities talents, so long as logical reasoning and linguistic facility are then also termed talents.

INTELLIGENCE TESTING

A brief history of intelligence tests

The Stanford–Binet test

In 1904, Binet and Simon were commissioned by the French government to devise a test which would identify those children who wouldn't benefit from ordinary schooling because of their inferior intelligence. The result was the Simon–Binet test (1905), generally accepted as the first intelligence test. The sample of children used for the development of the test (the *standardisation sample*) was very small, and it was subsequently revised in 1908 and 1911, using much larger samples.

Alfred Binet (1857–1911)

In 1910, Terman, at Stanford University in California, began adapting the Simon–Binet test for use in the USA. The test became known as the *Stanford–Binet* test, and is still referred to in this way. The first revision was published in 1916, followed by the Terman–Merrill revision (1937), which comprised two equivalent forms (L and M). In 1960, the most useful questions from the 1937 revision were combined into a single form (L–M) and an improved scoring system was used. Prior to 1960, the Stanford–Binet test was designed for individuals up to age 16 (starting at two-and-a-half to three), but this was extended to 18 in the 1960 revision.

A further revision was published in 1973, and the most recent in 1986, which is designed for people from age two years up to 23 years, 11 months. Subtests assess verbal reasoning, quantitative (mathematical) reasoning, abstract and visual reasoning, and memory. The testee is given a vocabulary test that serves as a routing test to determine the starting level for all the other scales (Sparrow & Davis, 2000).

In the 1986 revision, items are grouped into four broad areas of intellectual ability: (i) verbal reasoning; (ii) abstract/visual reasoning; (iii) quantitative reasoning; and (iv) short-term memory. A separate score is obtained for each area (whereas previously a single overall IQ score was given).

The Wechsler tests

Wechsler developed the most widely used test of adult intelligence, the Wechsler adult intelligence scale (WAIS, 1944), revised in 1958 and again in 1981 (WAIS-R). WAIS-III (1997) is designed for use with adults aged 16–89. Like WAIS-R, WAIS-III is constructed much like the Wechsler intelligence scale for children (WISC). This was first published in 1949 and revised in 1974 (WISC-R), and again in 1991 (WISC-III), and is designed for children between 5–15 years. Finally, the Wechsler preschool primary scale of intelligence (WPPSI, 1963; WPPSI-R, 1989) is designed for four- to six-and-a-half year olds.

The Wechsler tests produce three IQ scores: *verbal, performance,* and *full* (combined or general) IQs. Although there's much debate about the *atheoretical* nature of all the Wechsler tests, they're by far the most widely used cognitive assessment instruments today, both in the USA and around the world, having been translated into French, Greek, Japanese and Chinese (Sparrow & Davis, 2000) (see Table 41.3, page 714).

Army alpha and beta tests

The Stanford–Binet and Wechsler tests are *individual tests* (i.e. given to one person at a time). *Group tests* are administered to several people at once (as in written exams.) A major impetus to the development of group testing was America's involvement in World War I. A quick and easy method of selecting over one million recruits was needed, and the result was the *army alpha* and *beta tests* (see Gould, 1981).

The British ability scales (BAS)

The *British ability scales* (Elliot *et al.*, 1979) were designed for use with two-and-a-half to 17-year-olds. Five major 'mental processes' are assessed, including retrieval and application of knowledge, and speed of information-processing. The latter is meant to underlie performance on all the other subscales, and is one of the novel features of the test, reflecting the influence of the information-processing approach (see Chapter 34).

Like the Wechsler scales, the BAS gives three IQ scores – verbal, visual, and overall (general) IQs. In keeping with Thurstone's PMA model, the aim was to construct an intelligence scale which would provide a profile of special abilities, rather than merely produce an overall IQ figure (Richardson, 1991).

The original British test was revised and standardised in the USA as the *differential abilities scale* (Elliott, 1990), although it's used mainly in the UK. Its British revision (BASII, 1996, cited in Sparrow & Davis, 2000) was based on a new standardisation sample of 1700 British children, and the upper age limit is now 17 years, 11 months. Scales are now clearly divided into *early years* (2 years, 6 months to 5 years, 11 months) and school age (6 years to 17 years, 11 months).

Box 41.3 Some differences between individual and group tests

- *Individual tests* are used primarily as *diagnostic* tests in a clinical setting (for example, to assess the ability of a child with learning difficulties (see Chapter 40). *Group tests* are used primarily for *selection* and *research* purposes. For example, until the mid-1960s the eleven-

Table 41.3 Some items from the Stanford–Binet (1973) and the two scales of the WAIS-R (1981)

Stanford–Binet	Wechsler adult intelligence scale (WAIS-R)
Children of three should be able to: Point to objects that serve various functions (e.g. 'goes on your feet') Repeat a list of two words or digits (e.g. 'can', 'dog') **Children of four should be able to:** Discriminate visual forms (e.g. squares, circles, triangles) Define words (e.g. 'ball', 'bat') Repeat 10-word sentences, count up to four objects, solve problems (e.g. 'In daytime it is light, at night it is ...') **Children of nine should be able to:** Solve verbal problems (e.g. 'Tell me a number that rhymes with tree') Solve simple arithmetic problems and repeat four digits in reverse order **Children of twelve should be able to:** Define words (e.g. 'skill', 'muzzle') Repeat five digits in reverse order Solve verbal absurdities (e.g. 'One day we saw several icebergs that had been entirely melted by the warmth of the Gulf Stream. What's foolish about that?')	**Verbal scale** (none of the subtests is timed): • **Information**: general knowledge • **Comprehension**: ability to use knowledge in practical settings (e.g. 'What would you do if you were lost in a large, strange town?') • **Arithmetic** • **Similarities**: conceptual and analogical reasoning (e.g. 'In what ways are a book and TV alike?') • **Digit span**: STM (e.g. repeating a string of digits in the same/reverse order) • **Vocabulary**: word meaning **Performance scale** (all subtests are timed): • **Picture completion**: assessment of visual efficiency and memory by spotting missing items in drawings • **Picture arrangement**: assessment of sequential understanding by arranging a series of pictures to tell a story • **Block design**: ability to perceive/analyse patterns by copying pictures using multicoloured blocks • **Object assembly**: jigsaw puzzles • **Digit symbol**: ability to memorise and order abstract visual patterns

plus examination determined the kind of secondary schooling that every child in England and Wales would receive. It consisted largely of an intelligence test, designed largely to assess *g*.

- *Individual tests* usually involve some *performance items* (as in the Wechsler performance scale: see Table 41.3). *Group tests* are 'pencil-and-paper' tests, and in this way are much like other written exams.

ASK YOURSELF...

- Can you think of some advantages and disadvantages of individual and group tests?

- *Individual tests* are much more time-consuming than group tests, and can be administered only by specially trained testers – usually educational or clinical psychologists (see Chapter 1). There's some degree of flexibility as to how the test is conducted (such as how long the child is allowed to relax before the test proper begins), and some room for interpreting the child's answers.
- *Group tests*, which are timed, can be administered by teachers, researchers, and other non-trained personnel. Marking is usually done using a special marking key or by computer. In this respect, group tests are more *objective*.

What do intelligence tests measure?

IQ tests represent one kind of *ability* test, designed to measure underlying constructs that aren't a direct result of training (Coolican *et al.*, 1996). This contrasts with *attainment* (or *achievement*) tests (such as tests of reading and comprehension, spelling, and numeracy) designed to assess *specific* school learning. *Aptitude* tests are aimed at measuring *potential* performance (such as a logic test aimed at predicting how good someone would be at computer programming). Gottfredson (1998) describes IQ tests as tests of 'mental aptitude rather than accumulated knowledge' or 'pure *g*'.

The relationship between intelligence and IQ

ASK YOURSELF...

- Try to formulate some arguments for and against the claim that IQ is a valid measure of intelligence.

From the *psychometric* perspective, an individual's score on an intelligence test (his/her intelligence quotient or IQ) is an accurate measure of his/her intelligence. Effectively, and implicitly, an *operational definition* of intelligence is made (see above, page 706). But this begs many fundamental questions, relating to the *meaning* of the IQ (first introduced by Stern in 1912).

What kind of concept is IQ? Ratio and deviation IQs

Before 1960, the Stanford–Binet test calculated IQ by expressing *mental age* (MA) as a ratio of *chronological age* (CA) and multiplying by 100 (so as to produce a whole number). Hence, the first IQ was a *ratio IQ*. The Wechsler tests have instead always used a *deviation IQ*. This expresses the test result as a *standard score,* that is, it tells the tester how many standard deviations (SDs) above or below the mean of the testee's age group the score lies. Although all tests are designed in such a way as to produce a normal curve (a symmetrical distribution of IQ scores with a mean of 100), the SD (or dispersal of the scores around the mean) can still differ from test to test.

Box 41.4 Demonstrating the difference between intelligence and IQ

- Imagine two tests, A and B. Test A has a standard deviation (SD) of 10, and test B has a SD of 20. In both cases, 68 per cent (approximately) of children would be expected to have scores one SD below or above the mean (i.e. between 90 and 110 in test A, and between 80 and 120 in test B).
- So, a particular child might have a score of 110 on test A and 120 on test B, and yet the scores would be telling us the same thing.

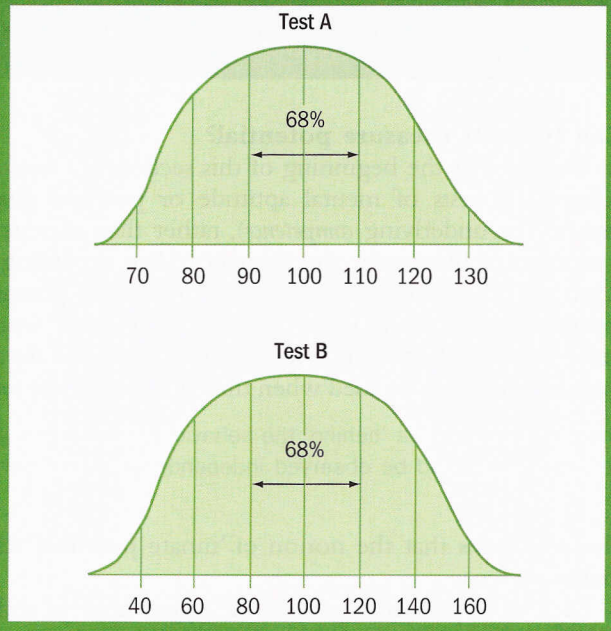


Figure 41.3 Normal curves of two hypothetical IQ tests, each with a different standard deviation

This suggests that while intelligence is a *psychological* concept, IQ is a purely *statistical* concept. If it's possible for the same characteristic (intelligence) to be assigned different values according to which test is used to measure it, then instead of asking 'How intelligent is this individual?, we should ask 'How intelligent is this individual as measured by this particular test?'. Since the IQ score of the same individual can vary according to the SD of the particular test being used, we cannot equate 'IQ' with 'intelligence'.

How is IQ measured? Ordinal vs interval scales

While an operational definition of, say, someone's height is uncontroversial, in the case of intelligence there's a genuine debate concerning what it *is* – and unless we know what it is, we cannot be sure we're measuring it properly. In agreeing with Heim that to name the particular test used is merely to reduce the circumference of the circle represented by an operational definition (see page 706), we could take this a step further by saying that for each separate test there exists a separate circle!

According to Ryan (1972), IQ creates the impression that we know in some absolute way what an individual's intellectual ability is. But unlike height, which is measured on an *interval* or *ratio scale,* IQ is measured on an *ordinal* scale, which tells us only whether one person is more or less intelligent than another (it's a *relative* measurement). We can measure one person's height accurately without knowing anyone else's, but the purpose of IQ tests is always to *compare* people's scores with those of others from the same population and of approximately the same age (Grigorenko & Sternberg, 2003: see below). (The BAS claims to give 'direct estimates of ability' (that is, it claims to use interval scaling), as if by a dipstick or linear rule, but Richardson (1991) doubts that this claim is valid.

Are IQ tests properly standardised?

Standardisation requires testing a large, representative sample of the population for whom the test is intended, otherwise the resulting norms cannot be used legitimately for certain groups of individuals. In the 1960 revision of the Stanford–Binet test, Terman and Merrill took only the population included in the census as their reference group, which excluded many migrant and unemployed workers.

More seriously, both tests were standardised on whites only, and yet they were to be used with both black and white children. As Ryan (1972) says, these tests are therefore tests of white abilities. This means that any comparison between black and white children is really an assessment of 'how blacks do on tests of white intelligence'. The 1973 revision of the Stanford–Binet did include black children in the 2100-strong standardisation sample.

Are IQ tests valid?

ASK YOURSELF...

- What do you understand by the validity of a psychological test?
- What does it mean in the context of intelligence?

A test is valid if it measures what it claims to measure. In relation to intelligence tests, the question is 'Do they measure intelligence?'. There are different kinds of validity and ways of measuring it (see Coolican, 2004), but probably the most commonly used in relation to psychological tests in general, and IQ tests in particular, is *predictive validity* (or *efficiency*). This refers to the correlation of a test with some future criterion measure, and the most common and powerful external criterion is *educability* or *educational success*. Also important is occupational success.

Before 1937, the mean score of women on the Stanford–Binet was ten points lower than that of men, and it was decided to eliminate this discrepancy by modifying the items so that average scores for men and women were the same. Heather (1976) asks why this hasn't been done with blacks. The answer lies in the test's predictive validity. Changing a test in order to eliminate racial differences, while not also changing social inequalities, would make the test a less efficient predictive tool. Removing the male–female bias did, in fact, make the test less efficient as a predictor of gender differences in educational and occupational success (Heather, 1976).

Do IQ tests predict educational success?

According to Gottfredson (1998):

> Intelligence as measured by IQ tests is the single most effective predictor known of individual performance at school and on the job. It also predicts many other aspects of well-being, including a person's chances of divorcing, dropping out of high school, being unemployed or having illegitimate children.

Typically, conventional IQ tests will correlate 0.4–0.6 with school grades. However, a test that predicts performance with a correlation of, say, 0.5, still accounts for only 25 per cent of the variation between the performance of different individuals (variation is calculated as the correlation squared = 0.5 squared = 0.25). This leaves 75 per cent of the variation unexplained, so there must be more to school performance than IQ! (Sternberg, 1998).

The predictive validity of tests declines when they're used to forecast outcomes in later life, such as job performance, salary, or obtaining the job in the first place. Generally, the correlations are just over 0.3, meaning that the tests account for roughly 10 per cent of the variation in people's performance. Also, the content of IQ tests has changed little from what it was at the beginning of the twentieth century (Sternberg, 1998).

According to Deese (1993): 'Tests have very modest correlations with performance in skills that society deems important', and Ceci & Liker (1986) claimed that 'IQ is unrelated to real-world forms of cognitive complexity'. However, teachers, doctors, accountants, pharmacists, lawyers and other professionals have a mean IQ above 120, while people in semi-skilled and low-skilled occupations (such as barbers, farm hands and labourers) score below 100 (Grigorenko & Sternberg, 2003). So, does IQ genuinely measure something worthwhile after all?

Box 41.5 What the predictive validity of IQ tests really means

- All the variables (including cognitive ability) that contribute to school success also contribute to performance on IQ tests. So, we'd expect a high correlation for this reason alone.
- Heather (1976) argues that 'general intelligence' can be called 'school intelligence', the ability to do well at school. Similarly, Richardson (1991) asks whether the correlation with school performance makes IQ tests valid tests of *educational prediction* rather than valid tests of intelligence.
- According to Ryan (1972), to the extent that tests measure educability, they're measuring something that is influenced to a considerable extent by various social and motivational factors. This conflicts with the test's purpose, namely to measure only cognitive ability or potential.
- According to Moghaddam (2002):

  ... a view of intelligence as inherently fixed and of society as being stratified on the basis of ability, so that those of lower intelligence remain at the lower levels and those of higher intelligence maintain their places at the top levels, is more likely to lead individuals to accept the status quo.

Can IQ tests measure potential?

As we noted at the beginning of this section, IQ tests are designed as tests of mental aptitude or potential (basic capacity or underlying *competence*), rather than as tests of attainment/achievement (performance). But according to Ryan (1972), it's logically impossible to measure potential separately from some actual behaviour. In other words, some of the skills that individuals have developed during their lifetime must be used when they do intelligence tests:

> There is nothing extra 'behind' the behaviour corresponding to potential that could be observed independently of the behaviour itself.

She concludes that the notion of 'innate potential' itself makes no sense.

Each of us presumably has some upper limit of ability (what we could do under ideal conditions, when we're maximally motivated, well, and rested). But everyday conditions are rarely ideal, and we typically perform below this hypothetical ability. Bee (1994) agrees with Ryan that it's not possible to measure competence, and so we're always measuring 'today's' performance. As Bee says:

> All IQ tests are really achievement tests to some degree. The difference between tests called IQ tests and those called achievement tests is really a matter of degree.

Are IQ tests culturally biased?

ASK YOURSELF...

- What do you understand by the terms '*culture-fair*' and '*culture-free*'?
- How do you think they might apply to IQ tests?

If the potential/achievement distinction is untenable in principle, it assumes even greater significance in the context of the debate concerning culture-fair and culture-free tests. According to Frijda & Jahoda (1966), a *culture-free* test would actually measure some inherent quality or capacity equally well in all cultures. There's no such test. A *culture-fair* test:

- could be a set of items which are equally unfamiliar to all possible persons in all possible cultures, so that everyone has an equal chance of passing (or failing) them (this is often called a *culture-free* test), or
- could comprise multiple sets of items, modified for use in each culture to ensure that each version would contain the same degree of familiarity; this would give members of each culture about the same chance of being successful with their respective versions.

The first option is virtually impossible. According to Segall *et al.* (1999), the second option is a theoretical possibility, but in practice it's very difficult to construct. Since the emphasis on language has been one of the more obvious sources of bias in traditional IQ tests, tests claiming to be culture-fair are often non-verbal. A well-known example is Raven's progressive matrices (see Figure 41.4).

However, the very nature of the task is something that is likely to reflect particular cultural experiences. Owen & Stoneman (1972) believe that because the influence of language is so pervasive, any attempt to devise a culture-fair test by removing 'overt language structures' is doomed to failure. Vernon (1969) rejects the idea of a culture-fair test.

ASK YOURSELF...

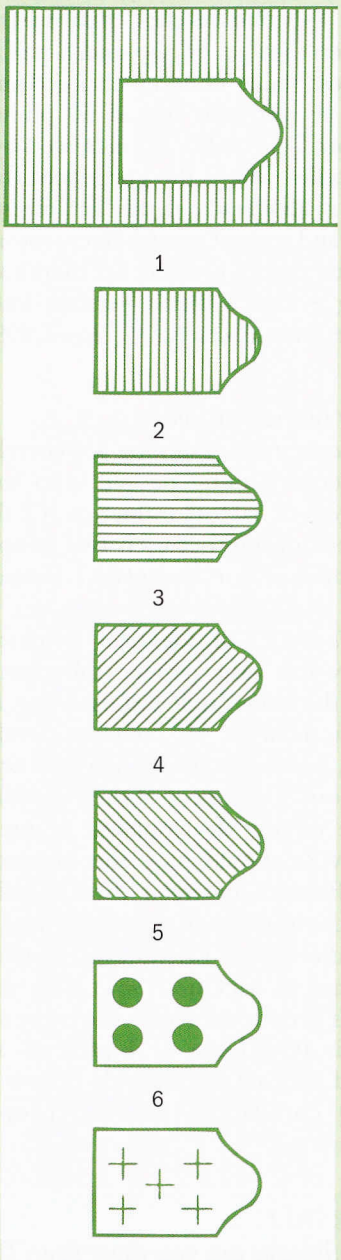

Figure 41.4 A sample item from Raven's progressive matrices test

- Even without any written instructions, you can probably infer what you have to do.

CRITICAL DISCUSSION 41.1 Intelligence as a cultural phenomenon

- A major reason that the construction of culture-fair tests has proved so problematical could be that the very notion of intelligence is itself culturally defined. For example, Bruner (in Gillham, 1975) maintains that:

  The culture-free test is the intelligence-free test, for intelligence is a cultural concept.

- Similarly, Gillham (1975) argues that any attempts to 'define' intelligence which don't involve identifying 'specially valued cultural attainments' must fail. The concept of intelligence derives its meaning only within a particular cultural and social context (see Sternberg's *contextual subtheory:* page 711).
- Something which can never be 'built-in' to a test's construction (or translation) is the meaning of the experience of taking an intelligence test. Taking tests of various kinds is a familiar experience for members of western culture (both within and outside education), but what about cultures in which there's no generally available schooling?
- The very nature or form of the tasks involved in an IQ test (as distinct from the content) is something that has

a cultural meaning. For example, Glick (1975, in Rogoff & Morelli, 1989) asked members of the Kpelle people to sort 20 familiar objects into groups. They did this by using *functional groupings* (such as knife with orange, potato with hoe), rather than taxonomic groups, which the researcher thought more appropriate. When their way of classifying the objects was challenged, they often explained that this was how a wise man would do it. When the exasperated researcher finally asked 'How would a fool do it?', the objects were immediately arranged into four neat piles of foods, tools, clothing, and utensils (i.e. *taxonomic groups!*). The Kpelle participants and the American researcher differed in their beliefs about the intelligent way of doing things.

- Different cultures may also promote the development of different abilities. For example, Serpell (1979) predicted that Zambian children would perform better than English children on a task in which they were required to copy objects using bits of wire. This was based on the observation that children all over central and southern Africa are very skilled at constructing wire cars from scraps of wire as a popular form of play. He also predicted that the English children would perform better when asked to draw the objects. Both predictions were supported, demonstrating that the abstract psychological function of pattern reproduction can be manifested in different ways according to the demands of the *ecocultural niche* to which participants' behaviour is adapted (Serpell, 1994).

We need to take culture into account when considering both the nature and the assessment of intelligence (Sternberg, 1995).

EXPLAINING INDIVIDUAL DIFFERENCES: HEREDITY AND ENVIRONMENT

According to Sternberg & Grigorenko (1997), virtually all researchers accept that:

- both heredity and environment contribute to intelligence
- heredity and environment interact in various ways
- extremely poor, as well as highly enriched, environments can interfere with the realisation of a person's intelligence, regardless of his/her heredity.

Genetic influences

Studies of IQ stability

Since people's genetic inheritance is a constant, then if measured intelligence (an IQ test score) is largely determined by genetic factors, there should be a high degree of continuity in IQ throughout a person's lifespan (McGurk, 1975). IQ isn't normally used as a measure of intelligence below age two. Instead, a *developmental quotient* (DQ) is used. This assesses a child's developmental rate compared with an 'average' child of the same age (Bayley, 1969). The younger a child is when given a developmental test, the lower the correlation between its DQ and later IQ. Once IQ is measurable, it becomes a better predictor of adult IQ.

Although the *stability coefficients* reported by some researchers (e.g. Honzik *et al.*, 1948) are impressive, they're based on large numbers of people and tend to obscure individual differences. Others have reported very low stability coefficients. For example, McCall *et al.* (1973) found that in 140 middle-class children, the average IQ change between the ages of two-and-a-half and 17 was 28 points. The most 'stable' children changed an average of 10 points, while 15 per cent shifted 50 points or more in either direction. One child's IQ increased by 74 points!

Even in studies where the correlation between IQ at different ages is statistically significant, the stability coefficients are low and suggest greater fluctuation in scores than a simple genetic theory predicts. So, there's a large amount of convincing evidence that a person's intelligence level can alter, sometimes substantially (Howe, 1997).

Family resemblance studies

Family resemblance studies examine the correlation in intelligence test scores among people who vary in genetic similarity. If genetic factors influence IQ, then the closer the genetic relationship between two people, the greater the correspondence (or *concordance*) between their IQs should be.

Monozygotic (MZ) or identical twins are unique in having exactly the same genetic inheritance, since they develop from the same single fertilised egg. *Dizygotic* (DZ) or non-identical twins, by contrast, develop from two fertilised eggs, and are no more alike than ordinary siblings (they share about 50 per cent of their genes). If genes have any influence on the development of measured intelligence, then MZs should have the highest concordance rates. Any difference between them would have to be attributed to environmental or experiential influences.

Many studies (e.g. Erlenmeyer-Kimling & Jarvik, 1963; Bouchard & McGue, 1981) have shown that the closer people's genetic similarity, the more strongly correlated are their IQs. Table 41.4 presents a summary of Bouchard and McGue's worldwide review of 111 studies reporting IQ correlations between people of varying genetic similarity.

ASK YOURSELF...

- What conclusions can you draw from Table 41.4 regarding the influence of genetic factors?

Table 41.4 shows that the closer the genetic relationship between two individuals, the stronger the correlation between their IQ scores. So, the correlation between

Table 41.4 Familial correlations for IQ. The vertical bar on each distribution indicates the median correlation. The arrow indicates the correlation predicted by a simple polygenic model (that is, the view that many pairs of genes are involved in the inheritance of intelligence) (based on Bouchard & McGue, 1981)

cousins (who share roughly 12.5 per cent of their genes) is weaker than that for parents and their offspring (who share roughly 50 per cent of theirs). The strongest correlation of all is for MZs. At first sight, these data suggest that heredity is a major influence on IQ test performance. However, as the genetic similarity between people increases, so does the similarity of their environments: parents and offspring usually live in the same households, whereas unrelated people don't. In other words, family resemblance studies *confound* genetic and environmental influences. In the case of comparisons between MZs and DZs, there's a unique problem regarding the role of environmental factors, namely the *equal environment assumption* (EEA).

CRITICAL DISCUSSION 41.2 The equal environment assumption (EEA)

- Within family resemblance studies as a whole, the MZ/DZ comparison is crucial. The greater concordance of MZs compared with same-sex DZs is taken to be the strongest evidence in favour of the genetic theory.
- This conclusion depends on the validity of the *equal environment assumption* (EEA) – that is, MZs and DZs experience (roughly) equal environments.
- But most people (including leading twin researchers) understand that MZs' physical and social environments are much more similar. This means that the higher concordance for MZs can tell us little about genetic influences on differences in intelligence (or any other psychological trait).
- However, supporters of the EEA (e.g. Shields, 1954; Kendler *et al.*, 1993; Scarr, 1968), while recognising that MZs *are* treated more similarly and experience more similar environments than DZs, claim that this is *caused by* their genetic similarity. In other words, twins 'create their own environment' (Plomin *et al.*, 1977).
- Joseph (2003) believes this is a 'heads I win, tails you lose' argument, which also rests on the further assumption that parents are readily able to change their behaviour and treatment of their twins based on environmentally caused factors (the twins' behaviour). Are adults that flexible? Wouldn't we expect their behaviour to be far *less* malleable than their children's?
- But even if the 'twins create their own environment' argument is valid, Joseph believes that the *reason* MZs experience more similar environments is completely *irrelevant*. He gives the hypothetical example of a twin study into possible genetic influences on lung cancer. Let's assume there's a genetic basis for the desire to smoke tobacco. Because of their greater genetic similarity, it's likely that MZs would be more concordant for cigarette smoking. According to Plomin *et al.*'s logic, since the tendency towards *smoking* is 'driven genetically', the higher MZ concordance for *lung cancer* is evidence of a genetic predisposition for lung cancer. This is clearly mistaken, because lung cancer could still be *completely* explained by exposure to tobacco smoke – an *environmental* event (Joseph, 2003).

Studies of separated twins

One way of overcoming the problem of family resemblance studies in general, and the EEA in particular, is to compare the IQs of MZs reared together in the same environments (MZsRT) with those raised separately in different environments (MZsRA). As Table 41.4 shows, MZsRT show a greater similarity in IQ scores than MZsRA. However, the fact that MZsRA are still more similar than same-sex DZsRT suggests a strong genetic influence (Bouchard *et al.*, 1990).

KEY STUDY 41.1 The Minnesota Study of Twins Reared Apart (MISTRA)

- This was started in 1979 by Bouchard and his colleagues at the University of Minnesota. Reports have been published since 1988.
- According to Bouchard (1984), each twin was given a Life History Interview, a Clinical Interview, a Sexual Life History Interview, a Life Stress Interview, a Child Rearing and Schooling Interview, and the Briggs Life History Questionnaire.
- As of 1998, Bouchard *et al.* have studied 71 pairs of MZsRA. They have been the subject of numerous articles, several books popularising the study of the influence of genetics on behaviour (*behaviour genetics research*), and TV programmes.
- A 1990 article compared MZsRA and MZsRT for physical variables, IQ and personality. Overall (combined) IQs on the WAIS (see page 713) showed correlations of 0.69 for MZsRA (48 pairs) and 0.88 for MZsRT (40 pairs). For personality, correlations were 0.49 for both groups. For other abilities, such as memory, the correlations are low or, as with spatial ability, inconsistent (Thompson *et al.*, 1991).
- Bouchard *et al.* concluded that psychological traits are strongly influenced by genetic factors. They were careful to test each twin separately and to have different testers administer the tests. They also vigorously recruited *all* twin pairs they became aware of, regardless of whether they were MZsRA or DZsRA.

ASK YOURSELF...

- Why do you think they took these precautions?

- Using different testers to test the twins separately ensured that the testers were 'blind' to the twins' identity – that is, they couldn't be (unconsciously) influenced by knowledge of the co-twin's score (*experimenter bias*) when testing the other co-twin. If they'd selected twin pairs *knowing* they were MZs or DZs, results could again have been biased, based on the assumption that MZs are psychologically more similar (*ascertainment bias:* Joseph, 2003).
- According to Bouchard & Loehlin (2001), only 'the most extreme sceptic' would dispute the finding that:

"...virtually all human psychological traits are influenced by genetic factors to a significant degree."

Barbara Herbert and Daphne Goodship, one of the pairs of (English) separated identical twins reunited through their participation in the Minnesota twin study

An evaluation of twin studies

According to Joseph (2003), despite the 'safeguards' described in Key Study 41.1, in many ways the MISTRA is methodologically *inferior* to earlier studies. These include Newman *et al.* (1937), Shields (1962), Juel-Nielsen (1965) and Burt (e.g. 1966), and they share many of the same methodological shortcomings as the MISTRA.

- 'Separated' twins often turn out not to have been reared separately at all. In Shields' and Juel-Nielsen's studies, some of the twins were raised in related branches of the parents' families, attended the same schools and/or played together (Farber, 1981; Horgan, 1993). When these are excluded from analysis in Shields's study, for example, the correlation decreases from 0.77 to 0.51. Moreover, even if the twins are separated at birth, they've shared the same environment of the mother's womb for nine months. Their identical prenatal experiences may account for the observed similarities in IQ (Howe, 1997). The MISTRA MZsRA were recruited partly on the basis of their pre-exiting knowledge of their co-twin.
- Studies of MZsRA are also *adoption studies,* and a critical assumption of all adoption studies is that children are placed *randomly* into available adoptive homes (see below). But when twins have to be separated, the agencies responsible for placing them generally try to match the respective families as closely as possible. Genetic inferences from such studies depend on the assumption that the twins' environments aren't systematically more similar than those of a group of randomly selected, biologically unrelated paired individuals (an *unequal environment assumption:* Joseph, 2003). When the environments are substantially

different, there are marked IQ differences between the twins (Newman *et al.*, 1937).

- In Newman *et al.*'s and Shields' studies, the experimenters knew which twins were identical and which had been separated. Participants in MISTRA were recruited by means of media appeals and 'self-referrals'. Kaprio (in Horgan, 1993) claims this has tended to attract people who enjoy publicity, and therefore constitute an *atypical sample* of MZsRA.
- Related to this is the fundamental question of whether MZs (whether reared together or apart) are representative of *people in general*. According to Joseph (2003), the only valid *control group* in a study involving MZsRA would be two randomly selected, biologically unrelated pairs of strangers matched on the same environmental variables shared by MZs. They are (by definition) exactly the same age, sex and (almost always) ethnicity, they're (usually) strikingly similar in appearance, which will probably elicit similar treatment, they're usually raised in the same socio-economic and cultural contexts, and so on. Plus, as we noted earlier, they've shared a womb for nine months before any of these post-natal factors begin to 'kick in'.
- Different studies have used different IQ tests, making comparisons between them difficult. Moreover, some of the tests used were inappropriate and/or not standardised on certain groups (see above).
- For a long time, the most widely cited and best-known studies of MZsRA were those reported by Burt (e.g. 1966), who found high correlations between the IQs of 53 pairs of twins supposedly reared in very different environments. After noticing several peculiarities in Burt's procedures and data, Kamin (1974) and Gillie (1976) questioned the genuineness of Burt's research. Even Burt's most loyal supporters have conceded that at least some of his data were fabricated (e.g. Hearnshaw, 1979).
- A problem unique to MISTRA is Bouchard *et al.*'s refusal to make the life history and tests score data available to other researchers (such as Kamin) for independent analysis. Yet during the 1980s, they provided information to journalists and others, which led to twins' stories appearing in leading US magazines and newspapers.

Adoption studies

Adopted children share half their genes but nothing of their environment with their biological parents, and they share at least some of their environment but none of their genes with their adoptive parents. One research methodology involves comparing the IQs of children adopted in infancy with those of their adoptive and biological parents.

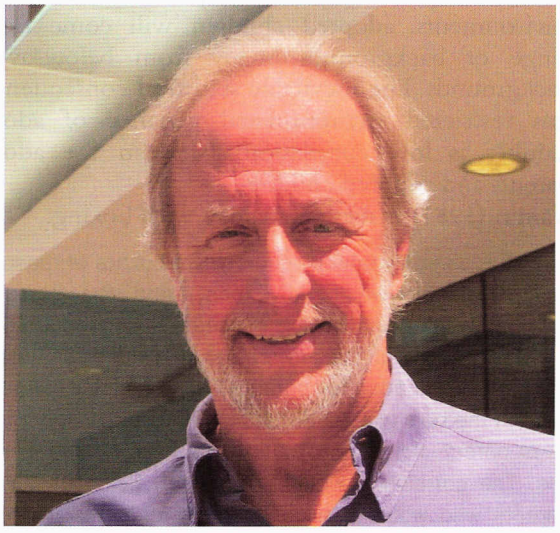
ASK YOURSELF...

- Using this research methodology, what outcome would lend support to the genetic theory (i.e. correlations between whom would need to be greater)?

Support for the influence of genetic factors would be obtained if the correlation between the adopted children's IQ scores and those of their *biological* parents was stronger than that between the adopted children and their adoptive parents.

This is exactly what some studies have shown. Munsinger (1975) found that the average correlation between adopted children and their biological parents was 0.48, compared with 0.19 for adopted children and their adoptive parents. Also, by the end of adolescence, adopted children's IQs are correlated only weakly with their adoptive siblings, who share the same environments but are biologically unrelated (Plomin, 1988).

An evaluation of adoption studies



- This finding (that the adopted children's IQs tend to correlate more with their biological than their adoptive parents) seems to be contradicted by the separate finding that the IQs of working-class children reared in middle- or upper-class families typically rise by 12 to 14 points. In general, supporters of the genetic theory focus on the former, while environmentalists emphasise the latter.
- According to Joseph (2003), the higher correlations between adopted children and their biological parents is an artefact of sampling, and can be explained in terms of the 'restrictive variance' of adoptive families (Kamin, 1981). They are similar in socio-economic status and have been carefully screened by the adoption agencies. So, while most adoptive parents are of above-average intelligence and provide above-average environments, adopted children will come from a range of backgrounds, many from below-average backgrounds. The inevitable statistical consequence of this restricted environmental variance of adoptive families is low correlations between the adoptive parents and adopted children.
- Kamin (1981) makes an analogy with boxing:

> ... Fights can only take place between boxers of reasonably similar weight [weight divisions], and the correlation between weight and boxing success is consequently very low ... in terms of the environment provided for their children almost all adoptive parents – unlike biological parents – are in the heavyweight division. That would account for the lower parent–child IQ correlation observed in adoptive families. The correlation would presumably be much higher if parents who would provide poor environments wanted to, and were allowed to, adopt more often.

- Studies relating to the second finding concerning big increases in the IQs of working-class children are described in Key Study 41.2.

KEY STUDY 41.2 Adoption studies involving very different natural and adoptive parental environments (Capron & Duyme, 1989; Scarr & Weinberg, 1976; Schiff *et al.*, 1978)

- Scarr & Weinberg's (1976) 'transracial' study involved 101 white families, above average in intelligence, income and social class, who adopted black children. If genetics were the only factor influencing the development of measured intelligence, then the average IQ of the adopted children should have been more or less what it was before they were adopted. In fact, their average IQ was 106 following adoption, compared with an average of 90 before adoption.
- Scarr and Weinberg's data also indicated that children adopted *early* (within their first year) have higher IQs than those adopted later. So, when adoptive homes provide a superior intellectual climate, they can have a substantial effect on the development of measured intelligence.
- But when the economic status of the biological and adoptive parents is roughly equal, the IQs of adopted children tend to be much more similar to those of the biological parents than the adoptive parents (Scarr & Weinberg, 1978).
- Schiff *et al.* (1978) studied a group of economically deprived French mothers who'd given up one baby for adoption while retaining at least one other child. The average IQ of the children adopted into middle class homes was 110, while that of the siblings who remained with the biological mother was 95.
- Similarly, French adoptees raised by parents of high socio-economic status (SES) were around 12 IQ points higher than adoptees raised by parents of low SES – irrespective of their biological parents' SES (Capron & Duyme, 1989).

Robert Plomin

- According to Schiff & Lewontin (1986):

> ... adopted children, even though they may correlate *individually* with their biological parents more than with their adoptive parents are, in fact, more similar *as a group* to the adoptive parents than to their biological ones.

- Plomin and DeFries's Colorado Adoption Project (begun in 1975) is an ongoing study involving over 200 adopted children. By middle childhood, natural (birth) mothers and their children who were adopted were just as similar as control parents and their children on measures of both verbal and spatial ability. In contrast, the adoptees' scores don't resemble their adoptive parents' at all.
- According to Plomin & DeFries (1998), these results are consistent with a growing body of evidence suggesting that the *shared family environment* doesn't contribute to similarities between family members:

> Rather, family resemblance on such measures [verbal and spatial ability] seems to be controlled almost entirely by genetics, and environmental factors often end up making family members different, not the same.

Environmental influences

While not denying the role of genetic factors, those who believe that the environment influences IQ identify a whole range of (pre- and postnatal) environmental factors.

Prenatal environmental influences

Prenatal non-genetic factors account for the largest proportion of biologically caused learning difficulties and lowered IQ. Known prenatal *teratogens* (any agent causing abnormalities in the developing foetus) include certain infections (e.g. maternal rubella), toxic chemicals in the mother's body (e.g. drugs like heroin, cocaine, and alcohol: see Box 40.7, page 698), radiation, and pollutants. Other toxins are produced by the mother's own faulty metabolism, or as a result of incompatibility

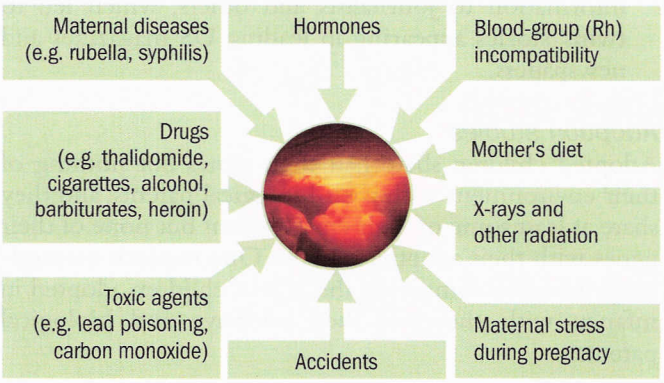


Figure 41.5 The prenatal, biological environment

between the rhesus factors in the mother's blood and that of her developing foetus (Frude, 1998).

Anxiety has also been found to lead to low birth-weight babies (due to impaired blood flow to the uterus: Teixeira, 1999). In turn, low birth-weight is associated with neurological impairment, lower IQ, and greater problems in school (e.g. Hack *et al.*, 1994).

Postnatal environmental influences

KEY STUDY 41.3 Romanian orphans (Rutter *et al.*, 1998)

- Rutter *et al.* studied a large sample of 111 institutionalised Romanian children adopted into English families within 24 months of birth. The children had experienced extreme privation, both physically and psychologically, and were all severely malnourished.
- Compared with 42 English adoptees, the Romanian children showed developmental deficiencies in weight, height, and head circumference, as well as deficits in reaching developmental milestones.
- However, by age four, they showed considerable physical and developmental catch-up (see Chapter 32), and 'spectacular' cognitive catch-up. Those who were adopted before six months had a clear advantage over the later-adopted children.
- Although their data don't allow a clear differentiation to be made, Rutter *et al.* conclude that the effects of malnutrition *don't* appear to be independent of the effects of the psychological privation.
- By age six, they'd maintained their progress, but there was no evidence of any further recovery (O'Connor *et al.*, 2000).

Other studies suggest that periodic or chronic subnutrition can adversely affect cognitive development in its own right. For example, when children in developing countries are given high-quality nutritional supplements in infancy and early childhood, their later IQ and vocabulary scores are higher than those of non-supplemented children (Pollitt & Gorman, 1994).

Environmental enrichment studies

Skeels (1966) followed up a group of children removed from orphanages into more stimulating environments 20 years earlier (Skeels & Dye, 1939). Most of those raised by foster mothers showed significant improvements in their IQs, whereas those raised in the orphanage had dropped out of high school, or were still institutionalised or not self-supporting. Other studies of children raised in orphanages have also shown that environmental enrichment can have beneficial effects. The Rutter *et al.* (1998) study of Romanian orphans is a striking example.

Hunt (1961) and Bloom (1964) argued that intelligence isn't a fixed attribute but depends on, and can be

Children at the Bloomingdale Day Center Headstart Program, New York City

increased by, experience. This led to President Johnson, as part of his 'war against poverty', initiating a number of *intervention programmes,* based on the assumption that intelligence could be increased through special training. The first of these was *Operation Headstart* (1965).

Operation Headstart (OH) was an ambitious compensatory programme designed to give culturally disadvantaged preschool children enriched opportunities in early life. It began as an eight-week summer programme, and shortly afterwards became a full year's preschool project. In 1967, two additional Follow Through programmes were initiated, in an attempt to involve parents and members of the wider community. Early findings indicated that there were significant short-term gains for the children, and this generated much optimism. But when IQ gains did occur, they disappeared within a couple of years, and the children's educational improvement was minimal.

KEY STUDY 41.4 The Milwaukee Project (Heber *et al.*, 1968)

- The Milwaukee Project is perhaps the most publicised of all the early intervention studies (Clarke & Clarke, 2000).
- Heber *et al.* found that mothers (living in the Milwaukee slum) with IQs under 80 (less than half the total of all mothers) accounted for almost 80 per cent of children with similarly low IQs.
- An intensive intervention programme involving 40 poor, mostly black families, began with the birth of their babies, and continued until the children started school at age six. 20 of the women were given job training and sent to school (the 'experimental group'), while the other 20 (the 'control group') received no job training or special education.

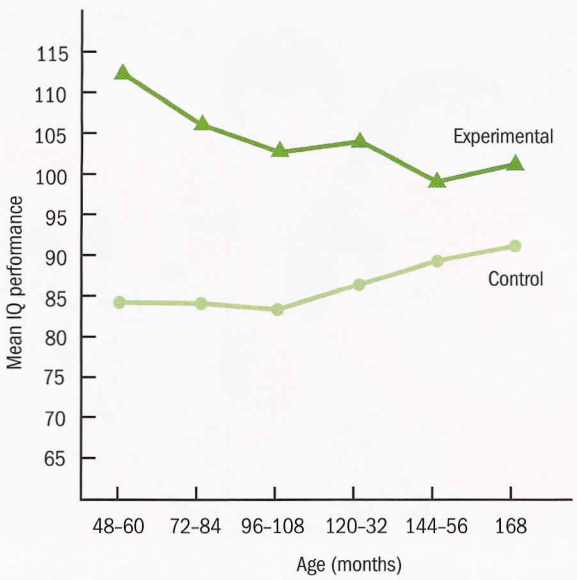

Figure 41.5 IQ performance with increasing age of severely disadvantaged children participating in a broad-ranging intensive intervention programme in the preschool years (data from Garber, 1988 and taken from Figure 6.5 (pp. 212–213) from *Developing Minds: Challenge and Continuity Across the Life Span*, by Michael Rutter and Marjorie Rutter (Penguin Books, 1992), copyright © Michael and Marjorie Rutter, 1992)

- At the point of starting school, the 'experimental group' children had an average IQ score of 120.7, compared with 87.2 for the control group. By age ten, these were 104 and 86 respectively. Educationally too, the experimental group was clearly superior.
- But after ten, both groups' performance fell below national norms, and over time the experimental group declined first to the lower levels of the city of Milwaukee, then still lower to the level of inner-city schools. When assessed at 12–14, mean IQs for the experimental and control groups were 100 and 90, respectively.
- Like OH, the Milwaukee project showed that vigorous and relatively prolonged intervention can make a difference to severely disadvantaged children's cognitive performances. But much of the gain is lost in the years following the end of the programme (Rutter & Rutter, 1992).

An evaluation of early intervention studies

- As the Milwaukee project was one of the most ambitious preschool programmes ever attempted, it raises the fundamental question of whether there can be any lasting benefits unless early intervention radically alters the whole context of family and other social and school relationships. Once the programme ended, all the adversities associated with poor social conditions and poor schooling provided an antidote to the earlier intervention (Clarke & Clarke, 2000).
- Hunt (1969) argued that OH was *inappropriate* to the children's needs, and didn't provide them with the skills they'd failed to develop at home during their first four years (and which are developed by most middle-class children). Also, IQ changes were the main outcome measure used to evaluate its effectiveness. Measures which reflect social competence, adaptability, and emotional health are much better criteria of success (Weinberg, 1989). According to Bee (2000), because children aren't randomly allocated to OH or non-OH, interpreting the differences becomes very difficult.
- However, the criticisms were apparently premature, and several reviews looking at OH's *long-term effects* have concluded that the programme has brought about lasting changes in children's cognitive abilities The greatest gains are shown by children with the lowest initial IQs. There's also a *sleeper effect* at work; that is, the impact of intervention programmes is *cumulative* (Collins, 1983).

Box 41.6 The longer-term effects of OH and other intervention programmes

Compared with non-participants, children enrolled in intervention programmes:

- will usually show gains of about 10 IQ points; these gains occur while the programme's running, but then fade and disappear within the early years of elementary (primary) school (Zigler & Styfco, 1993)
- are less likely to be placed in special education/remedial classes, are slightly less likely to repeat a grade, and slightly more likely to graduate from high school (Darlington, 1991; Haskins, 1989)
- tend to score higher on tests of reading, language and maths, with this 'achievement gap' widening between the ages 6 to 14 (Collins, 1983)
- show better school adjustment than their peers (Zigler & Styfco, 1993)
- are more likely to want to succeed academically (Collins, 1983).

- According to Bee (2000), although enrolled children don't necessarily test much higher than non-enrolled children, they function better in school. When some kind of supportive intervention continues into the early years of elementary school, and when the school is of a reasonable quality, the beneficial effects on school performance are even more evident (e.g. as in the Abcedarian Project: Ramey & Ramey, 1992).
- Howe (1997, 1998) believes that it would be inconceivable if the improvements in IQ produced by intervention programmes *didn't* fade. In the case of OH schemes, for example, the urban environments where they've been set up have often involved squalor, addiction, violence, unemployment, poor housing and inadequate parenting. Together, these

negative influences work to restrict a child's opportunities to practise and maintain recently acquired mental skills. This makes it highly likely that they'll fade (see Key Study 41.4).

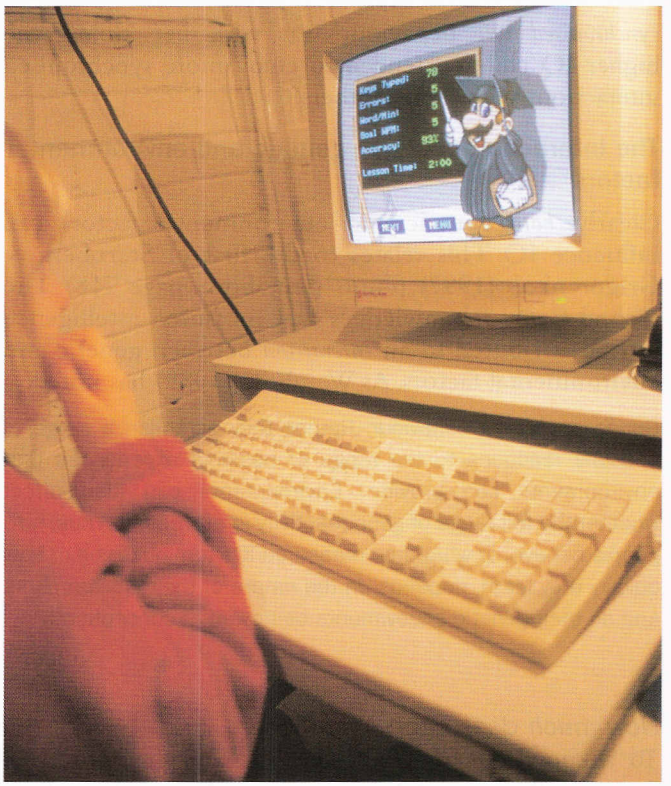
◎ For Howe, evidence of fading simply confirms that intelligence is changeable. Similarly, even if the vast majority of intervention studies had failed to raise children's IQs at all, this wouldn't be conclusive evidence that intelligence was fixed. Before 1972, the total amount of time a child would have spent in a OH programme was 180 hours. This rose to 720 hours after 1972. But when compared with real-life exposure to language of children from different social class backgrounds, 720 hours represents a rather modest intervention:

> Regarded in that light, the finding that educational intervention programmes ... have nevertheless yielded large ... IQ gains would appear to provide rather conclusive evidence that IQ scores are highly changeable ... (Howe, 1998)

Hothousing

ASK YOURSELF...

- Do you think it's possible, or indeed desirable, *deliberately* to speed up children's development?



Some psychologists believe that, while accelerated progress can occur in some areas, other skills (such as language) are essentially *preprogrammed* and not much affected by early experience (Howe, 1995; see Chapter 19).

Parents determined to make their child into a genius or prodigy can pressurise it with their high expectations, and by sending it to an organisation established to serve 'gifted children'. But there's no convincing evidence that such organisations are actually effective (Llewellyn-Smith, 1996). Also, children who experience intensive hothousing regimes may miss other experiences which, while not necessarily 'educational', are important for healthy development (Howe, 1995). A child who successfully completes a mathematics degree before the age of 14 has clearly developed a useful skill. But s/he might not have developed important social skills (such as the ability to make friends), because of an inability to join in 'normal' children's conversations (see Chapter 40).

Box 41.7 Dimensions of family interaction affecting cognitive development

According to Bee (2000), how infants and young children are treated can make a real difference to their cognitive development, regardless of whether they come from poor working-class or middle-class families. These differences in early experience have been the focus of most of the research into environmental effects on IQ. Parents of higher-IQ children, or whose IQs show an increase over time, tend to:

- provide interesting and complex physical environments, including play materials that are appropriate for the children's ages and developmental levels
- be emotionally responsive and involved with the children: smiling when the children smile, answering their questions, and generally responding to their cues
- talk to the children often, using language that's diverse, descriptively rich and accurate
- operate within the children's *zone of proximal development* (ZPD: see Chapter 34, page 594) during play and interaction
- avoid excessive restrictiveness, punitiveness, or control, providing opportunities for the children to ask questions, as opposed to giving commands
- expect their children to do well and develop rapidly, especially academically.

Computers can help make a child's environment more stimulating and challenging

A study relevant to Bee's second dimension was conducted by Crandell & Hobson (1999), involving 36 middle-class mothers and their three-year-olds. Children of securely attached mothers (based on a version of Main *et al.*'s, 1985, *adult attachment interview:* see Chapter 32) scored 19 points higher on the Stanford–Binet test compared with children of insecure mothers. In turn, a mother's attachment type was related to how well

Ruth Lawrence, who graduated with a first class degree from Oxford at the age of 13

synchronised her behaviour was with her child's: the higher-IQ children tended to enjoy more synchronised interactions with their mothers.

The interaction between genetic and environmental factors

Clearly, *both* genetic and environmental factors can influence IQ. This relates to the first of Sternberg & Grigorenko's (1997) points (see above, page 718). The second point acknowledges that measured intelligence can be attributed to an *interaction* between genetic and environmental factors. As Weinberg (1989) has noted:

> Genes do not fix behaviour. Rather, they establish a range of possible reactions to the range of possible experiences that environments can provide. Environments can also affect whether the full range of gene reactivity is expressed. Thus, how people behave, or what their measured IQs turn out to be or how quickly they learn, depends on the nature of their environments and on their genetic endowments bestowed at conception.

How much does each contribute?

To acknowledge that both genetic and environmental factors influence intelligence raises the question: how much does each contribute? *Behaviour genetics* attempt to determine the *relative* contributions made by genetic and environmental factors, and *heritability* refers to the mathematical estimate of how much variability in a particular trait is a result of genetic variability (Carlson, 1988). Eye colour, for example, is affected almost entirely by heredity and little, if at all, by environmental factors. As a result, the heritability of eye colour is close to 100 per cent. Early *heritability estimates* for IQ of 80 per cent (Jensen, 1969) have been revised more recently down to around 50–60 per cent (Bouchard & Segal, 1988).

What does heritability really mean?

- To say that the heritability of measured intelligence is 50–60 per cent *doesn't* mean that 50–60 per cent of measured intelligence is determined by genetic factors. This is because heritability estimates apply only to a particular *population* or group of people at a particular time – *not* to a single individual. So, of the variation in intelligence test scores within a group of people, about 50–60 per cent can be attributed to genetic factors (assuming Bouchard and Segal's estimate is correct).
- However, heritability describes what *is* rather than what *could be* (Pike & Plomin, 1999). If environmental factors within a population change (e.g. educational opportunities), then the relative impact of genes and environment will change. Even for a highly heritable trait such as height, environmental changes could make a large difference. Indeed, the huge increase in height during the twentieth century is almost certainly the result of improved diet (Pike & Plomin, 1999). As far as intelligence is concerned, heritability of 50 per cent means that environmental factors account for as much variance as genes do (Plomin & DeFries, 1998: see Chapter 50).

CRITICAL DISCUSSION 41.3 Heritability – a measure of inheritance or inherently misleading? (Joseph, 2003)

- Joseph argues that 'heritability' is perhaps the most misunderstood and misguided concept in the psychological (and psychiatric) literature.
- The calculation of a heritability estimate is based on the assumption that genes and environment *don't* interact; but clearly they do (and most behaviour geneticists would agree).
- For example, in the USA and UK, a person who is genetically coded to have dark pigmentation will usually experience a far different (inferior) environment compared with someone born with light skin, and four-feet-tall adult males will experience different environments than six-foot males.
- Even if the concept of heritability were valid and important for humans, the fact remains that heritability estimates are derived from family resemblance, twin and adoption studies, with all their associated problems and limitations (see text above).

How do heredity and environment contribute?

If we accept that genetic and environmental factors interact, then the focus shifts from how much they contribute to *how* they exert their influence. An example of how this might occur is *cumulative deficit*. Dozens of studies show that children from poor families, or families where the parents are relatively uneducated, have lower IQ scores than those from middle-class families (Bee, 2000). This could reflect either genetic or environmental factors, or both.

However, these social-class differences aren't found before the age of two-and-a-half to three, after which they widen steadily. This suggests that the longer a child lives in poverty, the more negative the effects on IQ test scores and other measures of cognitive functioning become (Duncan, 1993; Smith *et al.*, 1997). Hence, the effects of any genetic differences that may be involved to begin with are accentuated by environmental factors, especially poverty. Poverty has a significant effect on children's IQ scores over and above what the parents' own genes may have contributed (Bee, 2000).

The race and IQ debate

The false assumption that *between-group differences* can be inferred from *within-group differences* (see Box 41.8) forms a major part of the *hereditarian fallacy* (Gould, 1981). In turn, the fallacy is central to the claim that certain racial groups are genetically inferior to others.

Box 41.8 Why between-group differences cannot be inferred from within-group differences

- Lewontin (1976) asks us to consider 10 tomato plants grown in poor soil (see Figure 41.6 below). Their different heights are the result of genetic factors. If the same 10 plants were grown in fertile soil, differences in height would again be due to genetic factors.
- But the difference in the average height of the plants grown in poor and fertile soil is due to the *environmental* differences of the soils.
- So, even when the heritability of a trait is high *within* a particular group, differences in that trait *between* groups may have environmental causes (Myers, 1990).

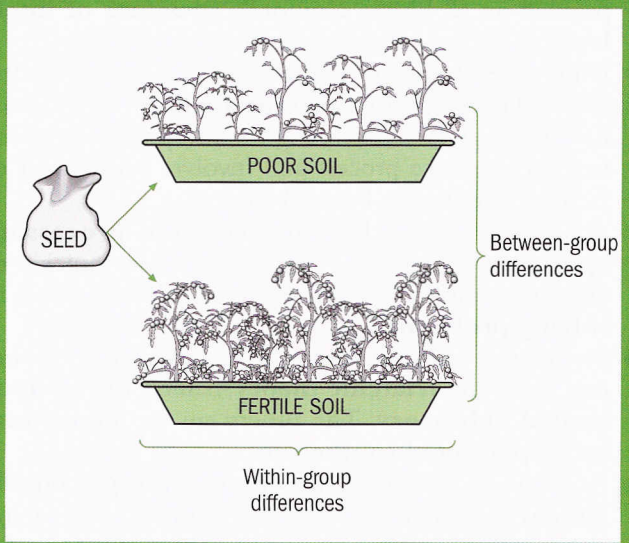


Figure 41.6 Although we can account for within-group differences in terms of genetic factors, between-group differences may be caused by environmental factors (i.e. poor/fertile soil)

Jensen (1969) published an article called 'How much can we boost IQ and scholastic achievement?', in which he reviewed all the literature which compared black and white IQ scores. The basic finding, that 'On average, Negroes test about one standard deviation (15 IQ points) below the average of the white population in IQ' is not itself a matter of dispute. What's controversial is Jensen's explanation of these findings:

> Genetic factors are strongly implicated in the average Negro–white intelligence differences. The preponderance of the evidence is, in my opinion, less consistent with a strictly environmental hypothesis than with a genetic hypothesis ... (Jensen, 1969)

Others, including Eysenck (1971) and Herrnstein (1971), agree with Jensen.

Some of the evidence on which Jensen based his genetic theory was the apparent failure of compensatory preschool programmes such as OH (see above). Perhaps the most fundamental criticism of Jensen is that he bases his view of black–white differences (between-group differences) on the heritability estimate (of 80:20) derived from studies of the white population (and so is based on within-group differences).

ASK YOURSELF...

- If we apply the argument in Box 41.8 to Jensen's (1969) claim that 80 per cent of the differences between blacks and whites on IQ tests are due to blacks' 'genetic inferiority', then his claim must be rejected. How else could you explain black–white differences?

Explaining race differences

Environmental factors which could account for such differences include *bias* in the tests used to measure intelligence. According to Segall *et al.* (1999), IQ tests are biased against those (such as blacks and other minorities) whose cultural backgrounds differ from that of the test's normative sample (whites). This relates to the earlier discussion of *culture-fair/culture-free* tests (see pages 717–718).

CRITICAL DISCUSSION 41.4 The political and racist nature of IQ tests

- According to Richardson (1998), the sex difference that was found prior to the 1937 Stanford–Binet test (see above) was accepted by Terman and Merrill as an undesirable artefact of the test items. The revision removed the sex differences because this was both possible and desirable.
- But what about race (and social class) differences? While these, too, *could* be eliminated, the reason they haven't been is that they're seen as real differences

existing in nature. In other words, the belief that races (and classes) are genetically inferior is built into most standardised IQ tests (Joseph, 2003). As Joseph says:

.. Items on standardised IQ tests do not fall from the sky; they are carefully selected (out of a large pool of potential items) to produce results desired by the test creator ...

- According to Sweet (2004):

... IQ tests remain a useful tool for racist ideologues ... Go to the website of Richard Lynn, Professor Emeritus at the University of Ulster – a man who believes ... not in 'genocide' but in the 'phasing out' of 'incompetent races' – and you'll find reams of ... racist pseudoscience ... His latest article ... 'presents new evidence ... [which] supports the theory that the proportion of white ancestry is a determinant of the intelligence of African-Americans ...'

It's perfectly possible, then, that individual differences in IQ (within-group differences) are heavily influenced by genetic factors, while group differences (between-group differences) are largely or entirely the result of environmental factors (such as test bias and other forms of discrimination). Jensen's response to this is to appeal to studies in which environmental factors are controlled.

For example, Shuey (1966) compared middle- and working-class blacks and whites and found the same average 15-point difference. But isn't there more to 'environment' than social class (measured largely in terms of occupation and income)? Given their history of slavery and continuing prejudice and discrimination, surely the experiences of working-class and middle-class blacks cannot be considered equivalent to that of their white counterparts. According to Bodmer (1972):

Measuring the environment only by standard socio-economic parameters is ... like trying to assess the character of an individual by his height, weight and eye colour.

CONCLUSIONS

By the late 1980s, the size of the black–white IQ gap had significantly narrowed – by about half to 7–8 points (Williams & Ceci, 1997) – although this trend didn't seem to continue into the 1990s. Closure of the gap seems to reflect increases in educational spending throughout the twentieth century, increased educational attainment by black parents, and reduction in the size of black families (Price & Crapo, 1999).

As important as these socio-economic factors are, both genetic and environmental factors can influence the development of IQ. These factors are intertwined, not separate. According to Segall *et al.* (1999):

... no behaviour is determined solely by culture or solely by biology. The two major classes of behavioural determinants always operate in such an interactive manner that they are difficult to separate. For intelligence, as for any other human characteristic, biological factors provide a broad range of potential and the outer limits or constraints of that potential, but experience has much room to operate within those limits.

According to Moghaddam (2002), intelligence isn't a single entity, but

... a social construct, with a multitude of different manifestations that can, and often do vary across groups and cultures ... As an alternative to viewing intelligence as a performance capacity – something fixed, inherited, and independent of context – we should view it as performance style, a way of doing things (solving problems) that is intimately related to context ...

CHAPTER SUMMARY

- Piaget's **biological** definition of intelligence sees it as related to **adaptation to the environment**. In contrast with his emphasis on the **qualitative** aspects of intelligence, the **psychometric approach** is concerned with **individual differences** in measured intelligence (**quantitative** aspects).
- According to Spearman's **two-factor theory**, every intellectual activity involves both a general factor (*g*) and a specific factor (*s*). Burt and Vernon's **hierarchical model** extended this by identifying **major** and **minor group factors**.
- Thurstone identified seven distinct **primary mental abilities** (PMAs). Instead of ranking individuals in terms of general intelligence, individuals should be profiled on all PMAs. Guilford's '**structure of intellect**' model also totally rejects the idea of *g*.
- Differences between British and American models reflect different forms of **factor analysis** (FA). Factors have to be given a psychological interpretation, which isn't an objective process and involves **reification** of factors once they've been labelled.
- According to the **information-processing approach**, people differ according to how quickly or efficiently they move through the steps involved in **solving problems**.
- Sternberg's information-processing model comprises one part of his **triarchic theory**, namely the **componential subtheory**. The others are the **contextual** and **experiential subtheories**.
- According to Gardner's **theory of multiple intelligences**, intelligence is a collection of separate, independent but interacting **systems**. Criteria for distinguishing an independent intelligence include potential isolation by brain damage, an identifiable core operation, and the existence of idiots savants and other exceptional individuals.

- **Individual tests** of intelligence are used mainly as **diagnostic** tests in clinical settings, while **group tests** are used mainly for educational **selection** and **research**.
- Although all tests now use a **deviation IQ**, standard deviations (SDs) can still differ between tests. While intelligence is a **psychological** concept, IQ is a **statistical** concept.
- Both the **Stanford–Binet** and **Wechsler** scales were originally **standardised** on whites only, and the restandardisation of the former so as to equalise the mean scores of women and men reveals the **ideological significance** of IQ. This adjustment changes the test's **predictive validity** (or **efficiency**).
- A strictly **culture-free** test is impossible, while a **culture-fair** test is possible but very difficult to construct in practice. The very concept of intelligence is cultural, and no test can assess the meaning that the experience of taking an intelligence test has for the testee.
- Although several studies show high **stability coefficients** for IQ, these obscure sometimes very large individual differences, and there are many short-term fluctuations.
- As people's **genetic similarity** increases, generally so does the **similarity of their environments**. This can be overcome by comparing the IQs of MZs reared together (MZsRT) with those raised separately (MZsRA).
- MZsRA are still more similar than same-sex DZs reared together, suggesting a strong genetic influence. However, studies of MZsRA have been criticised on several important methodological grounds.
- Further support for the influence of genetic factors comes from **adoption studies**. But when children from disadvantaged parents are adopted into high socioeconomic families, substantial gains in IQ can occur.
- **Intervention programmes** started with Operation Headstart (OH). Early findings indicated significant short-term IQ gains, but these were short-lived and the educational improvements were minimal. Similar results were reported for the Milwaukee Project.
- Studies of the longer-term effects have concluded that OH has lasting cognitive benefits, especially for those whose IQ scores were initially the lowest. There's also a **sleeper effect**.
- **Heritability** refers to how much of the variability in a particular trait is due to genetic variability **within** a particular group/population. Even when heritability is high, differences in that trait **between** groups may have **environmental** causes.
- One assumption involved in the **hereditarian fallacy** is that heritability estimates based on **within-group differences** (such as are found in twin studies) can be applied to **between-group differences** (such as between blacks and whites).
- Trying to equate the environments of blacks and whites in terms of social class is invalid, and IQ tests are **racially biased**.

Links with other topics/chapters

- Piaget's view of intelligence as adaptation to the environment underlies his whole theory of *cognitive development* (Chapter 34).
- Using the noun 'intelligence' rather than the adjective 'intelligent' is an example of *reification* – that is, discussing some abstract concept (or *hypothetical construct*) as if it were *real*. Psychology as a discipline often falls into this trap, because so much of its subject matter ('the mind') can only be *inferred* from observable behaviour (Chapter 3). One of the aims of *social constructionism* is to expose and highlight examples of reification (Chapter 2).
- Factor analysis is just as important – and controversial – in relation to theories of *personality* (Chapter 42).
- The distinction between fluid and crystallised intelligence is crucial for understanding *cognitive changes in old age* (Chapter 39).
- The information-processing approach represents a major alternative to Piaget's theory of *cognitive development* (Chapter 34).
- The ability to deal with novelty (as in Sternberg's experiential subtheory) is a characteristic of *gifted children* (Chapter 40).
- If definitions of intelligence differ, then IQ is an unwarranted *reduction* of intelligence (something very diverse and complex) to a single number (Chapter 49).
- In relation to the equal environment assumption, the claim that twins create their own environment refers to *reactive gene–environment correlation* (Chapter 50).
- Bouchard *et al.* released selected information to journalists concerning separated MZs who'd signed an *informed consent agreement*. The researchers promised *not* to divulge information that could be traced to specific twin pairs, thus breaching the *confidentiality* principle (Chapter 48).
- The distinction between *shared* and *non-shared environments* illustrates the *interaction* between *genetic* and *environmental factors* (Chapter 50).
- Molecular genetic research involves the search 'for' actual genes responsible for human characteristics and abilities, such as intelligence and *schizophrenia* (Chapter 44). This corresponds to what Rose (1997) calls *reductionism as ideology* (Chapter 49).
- *Behaviour genetics* is central to the *nature–nurture debate* (Chapter 50).
- Cumulative deficit is one of many examples of *gene–environment interaction* (Chapter 50).
- The charge that IQ tests are biased against blacks and other minorities is related to the *emic–etic distinction* (Chapter 47).

PERSONALITY

INTRODUCTION AND OVERVIEW

However different they may be in other respects, most personality theories share the basic assumption that personality is something that 'belongs' to the individual: 'the appropriate unit of analysis for personality psychology is the person' (Hampson, 1995).

To the extent that each of us 'has' a personality that's stable and relatively permanent, our behaviour will be consistent from one situation to another. An alternative view is that behaviour is largely determined by situational factors and that it will vary considerably across situations. This is referred to as the *trait versus situation debate* or the *consistency controversy.*

Personality theorists differ with respect to whether they're trying to compare individuals in terms of a specified number of traits or dimensions common to everyone (the *nomothetic approach*), or trying to identify individuals' unique characteristics and qualities (the *idiographic approach*).

According to the *constructionist approach* (Hampson, 1995), personality is constructed, in the course of social interaction, from three elements: a person's *self-presentation* (the actor: see Chapter 22), the *perception* of this presentation by an *audience* (the observer: see Chapter 22), and *self-awareness* (the self-observer: see Chapter 33). To this extent, personality isn't merely an abstraction which helps to explain people's behaviour (it's not something people 'have'), but it's to do with how we relate to other people and deal with the world in general.

CLASSIFYING THEORIES OF PERSONALITY

ASK YOURSELF...
- Try to define 'personality'.

If we wish to identify some of the dimensions along which various theories differ, then a useful definition of personality would be:

... those relatively stable and enduring aspects of individuals which distinguish them from other people, making them unique, but which at the same time allow people to be compared with each other.

This definition brings into focus two key questions.

- Does personality consist of *permanent traits* or characteristics?
- Is the study of personality the study of *unique individuals,* or is it aimed at comparing individuals and discovering the factors which constitute *personality in general?*

Psychologists who answer 'yes' to the first question, and who are interested in personality in general, belong to the *psychometric tradition* (*type* and *trait theorists*). The major figures are Eysenck and Cattell. They use personality questionnaires and the results from these are analysed using *factor analysis* (FA): see Chapter 41. In trying to establish factors in terms of which everyone can be compared, they adopt a *nomothetic approach.*

Psychologists who believe in the uniqueness of every individual adopt the *idiographic approach,* but beyond this it's difficult to say what else they have in common. For example, they may or may not see personality as permanent, or may differ as to how much or what kinds of change in personality are possible. But they're concerned with the *whole person,* whereas psychometric theorists want to rank or order individuals with respect to particular aspects of personality. Idiographic theorists include Allport, Kelly (whose *personal construct theory* isn't so much a theory of personality as a total psychology), and the *humanistic* psychologists Maslow and Rogers. Humanistic theories share a concern for the characteristics which make us distinctively human, including our experience of ourselves as people.

The *psychodynamic* theories of Freud and Jung are clearly idiographic: they're based on case studies of patients in the clinical context of psychotherapy and aren't concerned with measuring personality. However, they're also concerned with the nature of personality and try to account for individual differences. For example, Jung was the first to distinguish between introverts and

Table 42.1 A classification of personality theories

	Behaviour seen as consistent due to enduring personality traits. Change unlikely or impossible.	**Behaviour seen as variable due to the influence of situational factors. Personality change is possible.**
	Psychodynamic theories e.g. Freud, Jung, Adler and Erikson	
Nomothetic	Type and trait theories e.g. Eysenck and Cattell	'Situationism' e.g. Mischel
	Interactionism e.g. Bowers	
Idiographic	Allport's trait theory	Humanistic theories e.g. Rogers and Maslow
	Kelly's personal construct theory	

extroverts, which Eysenck later measured in his personality questionnaires. These theorists all allow for the possibility of personality change, primarily through psychotherapy.

NOMOTHETIC VERSUS IDIOGRAPHIC APPROACHES

ASK YOURSELF...

- Do you believe that every person is unique, or are we all basically the same, differing only in the degree to which we display certain tendencies or characteristics?

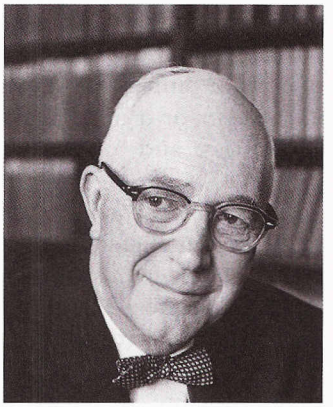
According to Kluckhohn & Murray (1953):

> Every man is in certain respects like all other men, like some other men and like no other men ...

What we have in common with *all* other human beings is the subject of experimental or 'general' psychology, which includes the study of cognitive and physiological processes, and learning. Much of developmental and social psychology is also concerned with discovering 'universal norms' which apply equally to all individuals.

What we have in common with *some* other human beings is examined through the study of *individual differences.* Personality differences represent one kind of *group norm,* others being age, gender, ethnic and cultural background, and intelligence. It's the study of 'how and how much a particular individual is similar to or differs from others' (Shackleton & Fletcher, 1984) which constitutes the factor-analytic/psychometric approach. As we've seen, this is also a nomothetic approach.

Finally, what we have in common with *no* other human being is the qualities that make us unique. This is the idiographic approach, which attempts to discover *individual/idiosyncratic norms.*



Allport's trait theory

Allport (1961) defined personality as:

> The dynamic organisation within the individual of those psychophysical systems that determine his characteristic behaviour and thoughts.

Allport & Odbert (1936) found over 18,000 terms describing personal characteristics and, even after omitting evaluative terms and transient states, there remained 4–5000. Allport believed that this large number of 'trait words' could be divided into just two basic kinds:

1. *common traits:* basic modes of adjustment applicable to all members of a particular cultural, ethnic, or linguistic background. For example, since we must all interact in a competitive world, we must each develop our own most suitable level of aggression. Each of us can be placed somewhere along a scale of aggressiveness. Common traits are the subject matter of the *nomothetic* approach
2. *individual traits:* a unique set of personal dispositions and ways of organising the world, based on life experiences. They're not dimensions which can be applied to all people. They cannot be measured by a standardised test, and can be discovered only by the careful and detailed study of individuals. Individual traits are the subject matter of the *idiographic* approach. Individual traits can take one of three forms: *cardinal, central,* or *secondary.*

Gordon W. Allport (1897–1967) (UPI/Bettmann Archive)

Box 42.1 Three kinds of individual traits

- **Cardinal traits** are so all-pervading that they dictate and direct almost all of an individual's behaviour, such as someone who's consumed by greed, ambition or lust. However, such traits are quite rare, and most people don't have one predominant trait.
- **Central traits** are the basic building blocks which make up the core of personality and which constitute the individual's characteristic ways of dealing with the world (e.g. honest, loving, happy-go-lucky). A surprisingly small number of these is usually sufficient to capture the essence of a person.
- **Secondary traits** are less consistent and influential than central traits, and refer to tastes, preferences, political persuasions, reactions to particular situations, and so on.

Individual traits are peculiar (idiosyncratic) to each person in at least three senses:

1. a trait that's central for one person may only be secondary for another person, and irrelevant for a third. What makes a trait central or secondary is determined not by what it is, but by how often and how strongly it influences the person's behaviour (Carver & Scheier, 1992)
2. some traits are possessed by only one person. Indeed, there may be as many separate traits as there are people
3. even if two different people are given, for convenience, the same descriptive label (such as 'helpful'), it

may not be used in the same way to describe both individuals and, to that extent, it's not the same trait. For Allport (1961), since personality dispositions reflect the subtle variations that distinguish a particular individual from all others, they must often be described at length, e.g. 'Little Susan has a peculiar anxious helpfulness all her own', instead of by a single label ('helpful').

This makes it very difficult to compare people:

> [Any given individual] is a unique creation of the forces of nature. There was never a person just like him and there never will be again ... (Allport, 1961)

Comparing people in terms of a specified number of traits or dimensions is precisely what the nomothetic approach involves: traits have the same *psychological meaning* for everyone, so that people differ only in the extent to which each trait is present. For example, Eysenck maintains that everyone will score somewhere on the extroversion (E) scale, and the difference between individuals is one of degree only (i.e. a *quantitative difference*).

For Allport (1961), people can be compared only in terms of common traits, which at best provide only a rough approximation to any particular personality. The nomothetic approach can only portray human personality in an oversimplified way: even the traits that people apparently share with one another will always differ from individual to individual.

Does the wholly unique individual exist?

Holt (1967) argues that the idiographic–nomothetic issue is based on a *false dichotomy*. All description involves some degree of generalisation, so that to imagine we can describe an individual in terms which make no reference to any other individual is a fallacy. To describe an individual, we must already have a concept of a person (a *schema* about people in general). As Kirby & Radford (1976) argue, a 'truly unique individual would be incomprehensible, in fact not recognisable as an individual'.

Disagreement between Allport and nomothetic theorists isn't so much to do with whether or not they believe in the idea of uniqueness, but rather how uniqueness is defined. Eysenck, for example, sees uniqueness as reflecting a particular combination of levels on trait dimensions, with the dimensions themselves being the same for all:

> To the scientist, the unique individual is simply the point of intersection between a number of quantitative variables ... (Eysenck, 1953, in Carver & Scheier, 1992)

For Allport, this is a definition of uniqueness based on common traits and is a contradiction in terms: only individual traits capture people's individuality.

According to Krahé (1992), the idiographic claim that there are unique traits that apply to only one individual is undoubtedly false, if taken literally. Traits are defined as *differential constructs* that refer to a person's position on a trait dimension relative to that of other people. But Krahé also believes that, at the opposite extreme, the nomothetic view of traits as explanatory constructs which apply to everyone is equally misguided.

Rather like Eysenck, Kline (1981b) believes that the existence of personality scales or questionnaires is compatible with the notion of uniqueness. In any particular sample, individuals will have very different profiles across a range of scales, but this doesn't mean they don't share certain characteristics with other members of the sample.

Is a science of unique individuals possible?

ASK YOURSELF...

- Is either the idiographic or nomothetic approach more compatible with the aims of science in general, and psychology in particular (as discussed in Chapter 3)?

Increasingly, psychologists are coming to believe that the idiographic and nomothetic approaches, far from being opposed and mutually exclusive, are *complementary* and interdependent (Krahé, 1992). Even Allport didn't reject the nomothetic approach completely. For example, when discussing the nature of psychology as a science, Allport (1960) says that:

> Science aims to achieve powers of understanding, prediction and control above the level of unaided common sense. From this point of view it becomes apparent that only by taking adequate account of the individual's total pattern of life can we achieve the aims of science. Knowledge of general laws ... quantitative assessments and correlational procedures are all helpful: but with this conceptual (nomothetic) knowledge must be blended a shrewd diagnosis of trends within an individual... Unless such idiographic (particular) knowledge is fused with nomothetic (universal) knowledge, we shall not achieve the aims of science, however closely we imitate the methods of the natural and mathematical sciences.

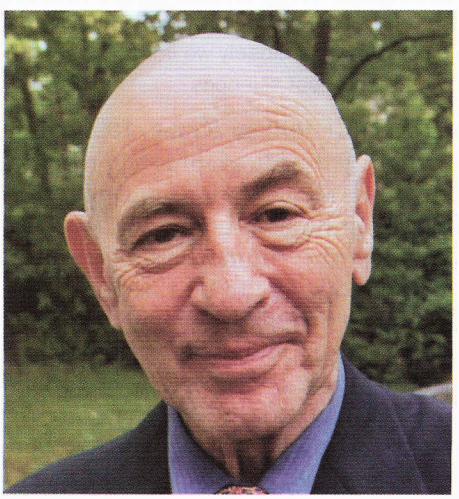
Jaccard and Dittus (1990, in Krahé, 1992) argue that it's untrue that a strictly idiographic approach is directly opposed to the identification and development of universal laws of human behaviour. The idiographic researcher, like the nomothetic, is interested in explaining behaviour, and to do this both seek a general theoretical framework that specifies the constructs that should be focused upon and the types of relationships expected among these concepts. The essential difference between the two approaches is that one applies the framework to a single person, while the other applies it to people in general. However, they share the same scientific aim.

Traits vs situations

Most definitions of traits focus on their stability and permanency, which implies that an individual's behaviour is consistent over time and from one situation to another. Indeed, Baron & Byrne (1991) define personality as:

> The combination of those relatively enduring traits which influence behaviour in a predictable way in a variety of situations.

ASK YOURSELF...



- According to the fundamental attribution error (FAE) and actor–observer effect (AOE), how are we likely to judge the consistency of our own and others' behaviour respectively? (See Chapter 23.)

The FAE involves attributing other people's behaviour primarily to their dispositional qualities (including personality traits). We're therefore likely to regard their behaviour as more consistent (and hence more predictable) than our own, which we see primarily as a response to the situation (AOE).

Seeing behaviour as being caused primarily by personality traits (the *trait approach*) is usually opposed to what has become known as *situationism* (Mischel, 1968) – the view that behaviour is largely determined by situational factors.

The consistency controversy

Mischel (1968), a social learning theorist (see Chapter 35), sparked the 'consistency controversy' by declaring that he could find very little evidence of *intraindividual* or *cross-situation consistency*. In other words, the same person tends to behave inconsistently in different situations – the opposite of what personality theorists would predict. He argued that the average correlation between different behavioural measures designed to tap the same personality trait was typically between 0.1 and 0.2, often lower, Correlations between scores on personality tests designed to measure a given trait and measures of behaviour in various situations meant to tap the same trait rarely exceeded 0.3.

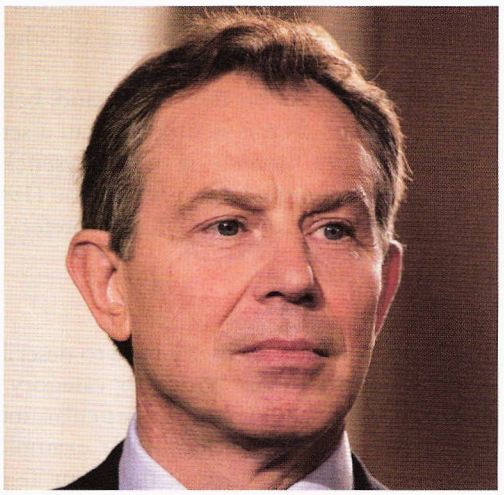
Walter Mischel (born 1930)

Box 42.2 Situationism

- Mischel took these very low correlations to indicate the importance of the situation in determining behaviour (*situationism*).
- If people behave inconsistently, the usefulness of the trait concept disappears and we're left only with situational influences to account for the inconsistency of individual behaviour. The same person behaves differently in different situations, because different situations require different behaviour and are associated with different kinds of reinforcements.
- So, from this (rather extreme) situationist perspective, *intraindividual inconsistency* is exactly what we'd expect!

ASK YOURSELF...

- Intuitively, does there seem to be anything wrong with situationism, at least in its extreme form?
- Surely different people behave differently even within the same situation and, conversely, aren't we recognisably the same person from one situation to another?



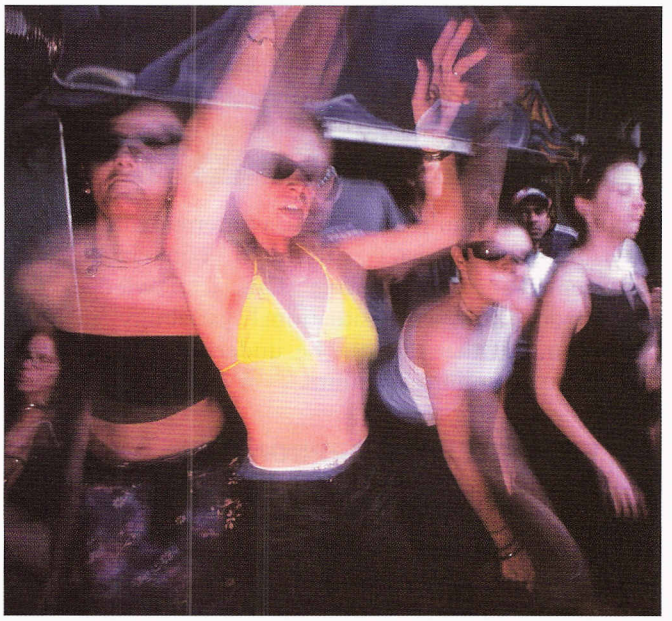
Evidence against situationism

Eysenck & Eysenck (1980) and Kline (1983) cite a number of studies which demonstrate consistency between scores on questionnaires and rating scales on the one hand, and behaviour on the other (average correlations of around 0.8). In addition, several writers have argued that to regard behaviour as being caused *either* by situational factors *or* by personality traits is an oversimplification of a complex issue. Bowers (1973), Endler (1975), and Pervin & Lewis (1978) all advocate an *interactionist* position, which stresses the mutual influence of situational and dispositional variables:

$$\text{Behaviour} = \text{Person} \times \text{Situation}$$

For example, Bowers reviewed 11 studies covering a wide range of behaviour, including aggression in young boys, anxiety in students, and resistance to temptation in children. He concluded that 13 per cent of the variance in participants' behaviour was due to *person variables*, 10 per cent to *situational variables*, and 20 per cent to an *interaction* between the two. While this kind of research cannot determine whether personality or situation is more important, the results nevertheless clearly favour the interactionist position (Argyle, 1983).

Tony Blair's pro-CND past is seen by some as incompatible with his current New Labour policies



The psychological situation

Mischel (1973) has moved towards a more interactionist position. But, in preference to traits, he talks about *social cognitive units* (or *person variables*). These incorporate a person's cognition, and the effect this has on his/her actions which are then assessed in relation to the situations in which they occur. They focus on what the person *does* (cognitively, affectively, and behaviourally), as opposed to what the person *has* in terms of traits, and include cognitive activities, encoding strategies, expectancies, values, preferences and goals.

Mischel believes that the same situation can have different *meanings* for different individuals, depending on past learning experiences. This determines how we select, evaluate, and interpret stimuli and, in turn, how particular stimuli affect our behaviour. It follows that situational factors on their own cannot account adequately for human behaviour, because they don't exist objectively, independent of the actor. Based on a study of children's ability to resist temptation when looking at attractive sweets, Mischel (1973) concluded that:

> The results clearly show that what is in the children's heads – not what is physically in front of them – determines their ability to delay ...

So, the *psychological situation* constitutes a critical determinant of behaviour: the psychological meaning of a situation for the individual (how it's perceived) is a crucial factor in predicting behaviour and accounting for regularities in behaviour across situations (Krahé, 1992). Another sense in which the influence of situations cannot be defined objectively is that personality traits, in particular introversion–extroversion, dictate the choice of situations people expose themselves to (Eysenck & Eysenck, 1985).

Different people are attracted to different kinds of situation, making it difficult to define their influence objectively

Box 42.3 A cognitive-affective person system (Mischel & Shoda, 1995, 1998)

- Mischel and Shoda's cognitive–affective person system accounts for both intraindividual consistency and predictable patterns of variability across situations.
- For example, a person may be shy in small groups but an excellent public speaker. Viewed in purely trait terms, this pattern of behaviour would be cross-situationally inconsistent. But if the differences in the psychological situation are taken into account, it becomes meaningful and predictable. Speaking to a large audience doesn't require engaging personally with any one individual, whereas making conversation in small groups does.
- Situational factors now represent a moderating influence on individual differences. This is a more sophisticated response to Mischel's critique of traits than pure situationism, or even 'mechanistic interactionism', in which behaviour is seen as a function of combined but independent situational and trait factors (Hampson, 1999).

According to Hampson (1999), contemporary personality psychology isn't so much concerned with consistency as with *coherence*. This acknowledges that people do show cross-situational variability in their behaviour, but that this can be understood when other factors are taken into account.

THE PSYCHOMETRIC APPROACH

Factor analysis

As we saw in Chapter 41, *factor analysis* (FA) is a statistical technique, based on correlation, which attempts to reduce large amounts of data (such as scores on personality questionnaires) to much smaller amounts. Essentially, the aim is to discover which test items correlate with one another and which don't, and then to identify the resulting correlation clusters (or factors). A fundamental issue is: what's the smallest number of factors which can adequately account for the variance between participants on the measures in question?

Eysenck prefers an *orthogonal method* of FA, which aims to identify a small number of powerful, independent (*uncorrelated*) factors. Cattell's preference is for an *oblique* method, which aims to identify a larger number of less powerful factors, which aren't independent (they're *correlated* to some degree).

Since it's possible to carry out a further FA of oblique factors, they're referred to as *first-order factors* and the resultant regrouping of the oblique factors as *second-order factors*. In fact, Cattell has discovered a small number of second-order factors which correspond closely to Eysenck's three major second-order factors (see below). Eysenck's second-order factors are referred to as *types* (what Cattell calls *surface traits*) and Cattell's first-order factors as *traits* (or *source traits*).

Table 42.2 Differences between Eysenck and Cattell in their preferred method of factor analysis

	Eysenck	Cattell
Preferred method of FA	Orthogonal	Oblique
Level of analysis	Second order	First order
Description of factors	Types ('surface traits')	Traits ('source traits')

Both Cattell and Eysenck believe their own methods best reflect the psychological reality of personality, but there's no objective way of establishing that one is right and the other wrong. However, Cattell (1966) and Cattell & Kline (1977) argue that an orthogonal technique prevents the attainment of *simple structure:* each factor will correlate quite highly with a few other factors and very little or not at all with a large number of others. This makes each factor simple to interpret.

Guilford (1959), on the other hand, believes that a set of uncorrelated factors is simpler than a set of oblique or correlated ones (which is why Eysenck opts for an orthogonal technique). However, Kline (1981b) maintains that most factor analysts, in practice, prefer oblique factors.

Eysenck's type theory

What are 'types'?

The term 'type' was formerly used to describe people who belonged either to one group or category or another, so that it was impossible for a particular individual to be considered a member of both. For example, according to the ancient Greek theory of the 'Four Temperaments' or 'Four Humours' (Galen, second century AD), a person was either *choleric* (due to an excess of yellow bile), *sanguine* (due to an excess of blood), *melancholic* (due to an excess of black bile), or *phlegmatic* (due to an excess of phlegm).

These four humours are included in the inner circle of Eysenck's diagram, as shown in Figure 42.1.

According to Eysenck (1995), today the term 'type' is either not used at all, or reserved for combinations of traits that are found to correlate. For example, extroversion is a type concept based on the observed correlations of sociability, liveliness, activity, and so on. The search for a reliable and valid measurement of personality traits is only a first step: the traits we find aren't independent of each other but are correlated in certain patterns that suggest more complex entities that might be called types. But unlike Galen's four humours, Eysenck's types are *personality dimensions,* which represent continua along which everyone can be placed.

Eysenck's dimensions in fact constitute the highest level of a hierarchy (Cattell's 'surface traits'), with a number of traits at the next level down (Cattell's 'source traits'). Below that is a set of habitual responses (typical ways of behaving) linked to a particular trait. At the lowest level is a specific response (a response on one particular occasion: see Figure 42.2).

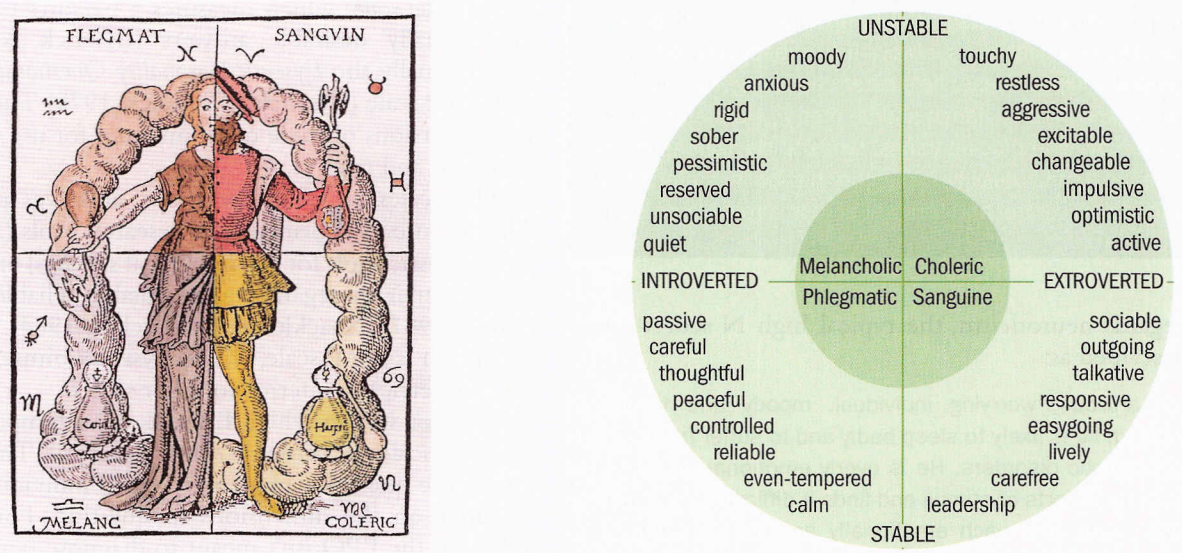


Figure 42.1 Personality has been dissected into component parts for thousands of years; what is interesting is how these ideas relate to the modern concept of personality traits, as shown by Eysenck's dimensions of personality (from Eysenck, 1965)

ASK YOURSELF...

- Which model of intelligence does Eysenck's personality theory remind you of (see Chapter 41)?

Extroversion (E), neuroticism (N) and psychoticism (P)

Eysenck (1947) factor-analysed 39 items of personal data (including personality ratings) for each of 700 neurotic soldiers, screening them for brain damage and physical illness. Two orthogonal (uncorrelated) factors emerged: *introversion–extroversion* (E) and *neuroticism (emotionality)–stability* (N). These two dimensions are assumed to be normally distributed, so that most people will score somewhere in the middle of the scale, and very few at either extreme. 'Typical' introverts and extroverts are 'idealised extremes' (or *ideal types*).

Box 42.4 Typical introverts and extroverts (Eysenck, 1965)

- The *typical introvert* is a quiet, retiring sort of person, introspective, fond of books rather than people; he's reserved and distant except to intimate friends. He tends to plan ahead, 'looks before he leaps' and distrusts the impulse of the moment. He doesn't like excitement, takes matters of everyday life with proper seriousness, and likes a well-ordered mode of life. He keeps his feelings under close control, seldom behaves in an aggressive manner, and doesn't lose his temper easily. He's reliable, somewhat pessimistic, and places great importance on ethical standards.
- The *typical extrovert* is sociable, likes parties, has many friends, needs to have people to talk to, and doesn't like reading or studying by himself. He craves excitement, takes chances, often sticks his neck out, acts on the spur

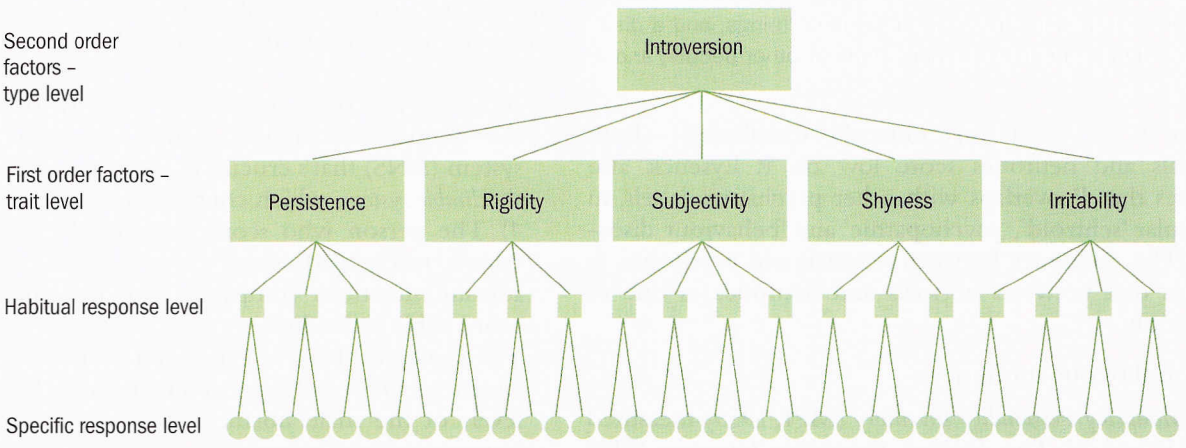

Figure 42.2 Eysenck's hierarchical model of personality in relation to the introversion dimension (after Eysenck, 1953)

of the moment, and is generally an impulsive individual. He likes practical jokes, always has a ready answer, and generally likes change; he's carefree, easy-going, optimistic and likes to 'laugh and be merry'. He prefers to keep moving and doing things, tends to be aggressive and lose his temper quickly; altogether his feelings aren't kept under tight control and he's not always a reliable person.

As regards neuroticism, the typical high N scorer could be described as:

... an anxious, worrying individual, moody and frequently depressed; he is likely to sleep badly and to suffer from various psychosomatic disorders. He is overly emotional, reacting too strongly to all sorts of stimuli and finds it difficult to get back on an even keel after each emotionally arousing experience ... (Eysenck, 1965)

By contrast, the typical low N scorer (stable) individual:

... tends to respond emotionally only slowly and generally weakly and to return to baseline quickly after emotional arousal; he is usually calm, even-tempered, controlled and unworried ... (Eysenck, 1965)

Since the original 1947 study, the existence of E and N has been supported by further research involving literally thousands of participants. Exhaustive research in many parts of the world, by many different researchers, has confirmed the existence of E and N, as well as a third dimension, *psychoticism* (P) (Eysenck & Eysenck, 1985). This was originally uncovered in a 1952 study of psychiatric patients, but is less well established than the other two dimensions. Just as E and N are unrelated to each other, so they are both unrelated to P. According to Eysenck & Eysenck (1975):

A high [P] scorer... may be described as being solitary, not caring for people; he is often troublesome, not fitting in anywhere. He may be cruel and inhumane, lacking in feelings and empathy, and altogether insensitive. He is hostile to others, even his own kith and kin, and aggressive, even to loved ones. He has a liking for odd and unusual things, and a disregard for danger; he likes to make fools of other people, and to upset them.

Unlike E and N, P isn't normally distributed – both normals and neurotics score low on P. Eysenck also believes that P overlaps with other psychiatric labels, in particular 'schizoid', 'psychopathic' and 'behaviour disorders'. The difference between normals and psychotics, as well as that between normals and neurotics, is one of *degree* only.

Personality questionnaires

The *Maudsley Personality Inventory* (MPI, 1959) measured both E and N. The *Eysenck Personality Inventory* (EPI) added a *lie scale,* which measures a person's tendency to give socially desirable answers (Eysenck & Eysenck, 1964). Finally, the *Eysenck Personality Questionnaire* (EPQ) added a P scale (Eysenck & Eysenck, 1975). There are also junior versions of these questionnaires for use with nine-year-olds and over.

The scales all comprise items of a 'yes/no' variety. They're intended primarily as research tools (as opposed to diagnostic tools for use in clinical settings) and, as such, they're generally regarded as acceptable, reliable, and valid (Kline, 1981a; Shackleton & Fletcher, 1984). The main exception is the P scale, which Eysenck himself admits is psychometrically inferior to other scales.

A major way in which Eysenck has attempted to validate his scales is through *criterion analysis.* This involves giving the questionnaires to groups of individuals known to differ on the dimensions in question. For example, although the EPQ isn't meant to diagnose neurosis, we'd expect diagnosed neurotics to score very high on N compared with non-neurotics – and generally this is found to be the case.

The biological basis of personality

Eysenck attempts to explain personality differences in terms of the kinds of nervous system individuals inherit.

- As far as E is concerned, what's crucial is the balance between excitation and inhibition processes in the central nervous system (CNS), specifically the *ascending reticular activating system* (ARAS: see Chapter 4). Its main function is to maintain an optimum level of alertness or 'arousal'. It does this by enhancing the incoming sensory data to the cortex through the excitation of neural impulses, or by 'dampening them down' through inhibition.

Extroverts have a 'strong nervous system'. Their ARAS is biased towards the *inhibition* of impulses, with the effect of reducing the intensity of any sensory stimulation reaching the cortex (they're *chronically under-aroused*). For introverts, the bias is in the opposite direction: the intensity of any sensory stimulation reaching the cortex is *increased* (they're *chronically over-aroused*).

- As far as N is concerned, it's the *reactivity* (or *lability*) of the sympathetic branch of the autonomic nervous system (ANS) that's crucial, in particular, differences in the *limbic system,* which controls the ANS (see Chapter 4). The person who scores high on N has an ANS which reacts particularly strongly and quickly to stressful situations compared with less emotional or more stable individuals.
- The biological basis of P is much more uncertain, but Eysenck (1980) has suggested that it may be related to levels of the male hormone, *androgen,* and/or other hormones (see Chapter 36).

Box 42.5 Evidence relating to biological differences between introverts and extroverts

- According to Eysenck (1967), extroverts become 'psychically fatigued' more easily (e.g. become bored more easily and persevere less) than introverts. According to Kline (1983), on long and tedious jobs extroverts should start better than introverts, do worse in the middle, and then improve again towards the end, while introverts should work much more steadily throughout. These hypotheses were supported by Eysenck (1967, 1971) and Harkins & Green (1975), who found that introverts do better at vigilance tasks, which require prolonged periods of concentration.
- In real life, extroverts change jobs and sexual partners more frequently than introverts, are more likely to divorce, show less brand loyalty in shopping behaviour, and move house more often (Eysenck, 1965; Eysenck & Eysenck, 1985).
- According to Eysenck (1970), introverts have lower pain thresholds and extroverts are more susceptible to the adverse effects of sensory deprivation. For example, one demonstration of the 'stimulus hunger' of extroverts is their willingness to go to great lengths to obtain a 'reward' of loud music or bright lights which introverts work hard to avoid.
- According to Hampson (1995), evidence for the role of the ARAS and arousal mechanisms in E is inconclusive, but great advances have been made since the mid-1980s in understanding the genetics of personality. As a result of large-scale twin, adoption, and family resemblance studies, it's now widely concluded that about 50 per cent of the variation in self-report personality measures may be due to heredity (Loehlin *et al.*, 1988). (But see Chapters 41 and 44 for a discussion of the limitations of family resemblance, twin, and adoption studies.)

Interaction between the biology of N and E

According to Claridge & Davis (2003), Eysenck never really worked out how *interaction* between the limbic system and ARAS takes place in practice. But one prediction, which has stood the test of time experimentally, concerns individuals who are high N and low E (anxiety neurotics in the clinical domain). According to Eysenck, they should have a double 'dose' of arousability: high activity in *both* the emotional brain (limbic system) and the brainstem (ARAS). The prediction that individuals high on N and low on E will show the most extreme responses on physiological measures (such as EEG and measures of ANS arousal) was confirmed by Claridge (1967). This established a strong biological connection between personality and at least one major group of psychological disorders (the anxiety disorders) (Claridge & Davis, 2003).

ASK YOURSELF...

- In terms of introverted and extroverted behaviour, what should be the effect of (a) stimulant and (b) depressant drugs (see Chapter 8)?
- Who should be easier to sedate – introverts or extroverts?

According to Wilson (1976), we'd expect introverts to be more difficult to sedate using a drug such as sodium amytal, because they're supposed to be more aroused. A particularly powerful technique involves *sedation/sleep threshold,* in which a barbiturate (which depresses the CNS) is injected by continuous infusion until the participants either go to sleep or reach some specified level of drowsiness (defined behaviourally or physiologically). The amount of drug needed is a measure of tolerance of sedation (Claridge & Davis, 2003).

Using this method, it's been repeatedly shown that anxiety neurotics, and their 'normal' counterparts (introverted neurotics or *dysthymics*), show extremely high drug tolerance (resistance to sedation) (Claridge & Herrington, 1960, 1962). Both groups were much more difficult to sedate than extroverted neurotics (*hysterics*), who are more easily sedated than normal participants (who score in the middle ranges on E and N).

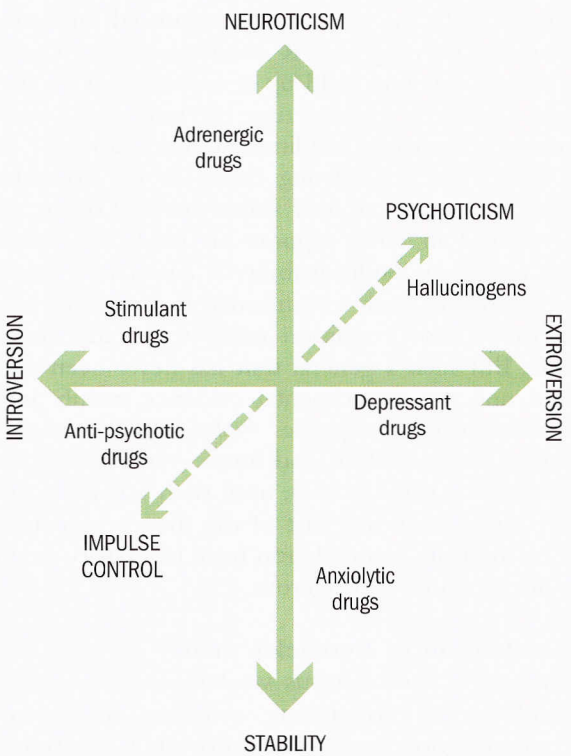

Figure 42.3 Drug addiction and personality (Eysenck, 1983). Source Eysenck, H.J. (1995) 'Trait theories of personality'. In S.E. Hampson & A.M. Coleman (Eds) *Individual Differences and Personality*. London, Pearson Education

Although nearly 50 years old, these studies still represent a valid observation about biology and the pharmacology of personality and psychological disorders (Claridge & Davis, 2003).

For the same reasons, regardless of an individual's normal position on the scale, *stimulant* drugs should shift behaviour in the direction of introversion, while depressant drugs (such as alcohol) should have the opposite effect.

Anxiolytic (*anti-anxiety*) drugs should increase emotional stability, *adrenergic* drugs (those which mimic the effects of adrenaline) should decrease it, *hallucinogens* should increase psychotic behaviour, and *anti-psychotic* drugs (*narcoleptics*) should decrease it. According to Eysenck (1995), empirical studies have, on the whole, supported these causal hypotheses (see Figure 42.3).

Personality and conditionability

ASK YOURSELF...

- Given what we've said so far about Eysenck's theory, how would you expect introverts and extroverts to differ regarding how easily they can be (classically) conditioned? (See Chapter 11.)

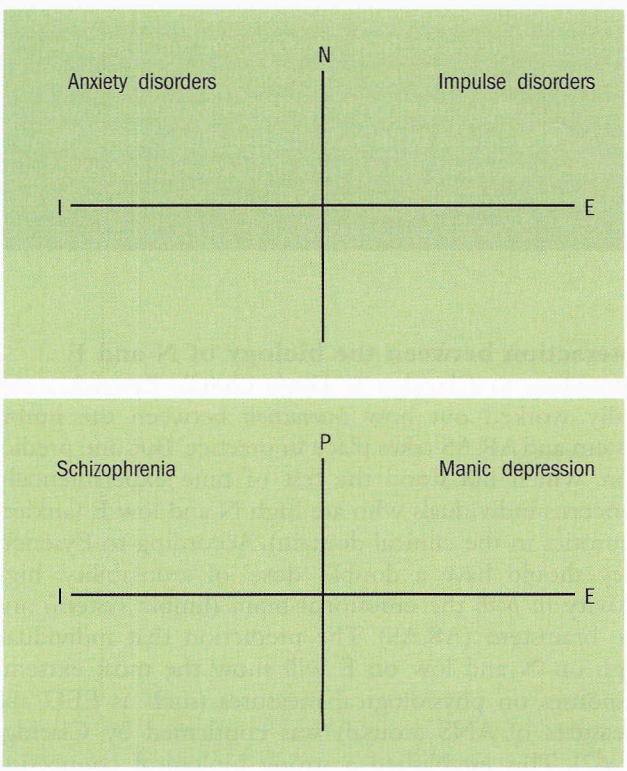
From a strictly psychological point of view, the importance of the biological aspects of Eysenck's theory is how they're related to individual differences in *conditionability*. Because extroverts require a stronger stimulus to make an impact compared with the more easily stimulated introvert, and because the learning of S–R connections is best achieved by a strong and rapid build-up of excitation in the nervous system (which is characteristic of introverts), introverts should be more easily conditioned than extroverts.

Despite Eysenck's strong claims to the contrary, the evidence is equivocal: only about one half of the studies he reviewed in 1967 support his predictions. Eysenck seems to regard conditionability as a unitary trait, that is, if introverts are easily conditioned to one kind of stimulus, they'll also condition easily to a range of other stimuli. But such a general trait has never been demonstrated, and the experimental evidence mainly involves three conditioned responses – the GSR (galvanic skin response), the eye blink, and simple verbal conditioning. According to Kline (1983), until such a general dimension is discovered, this part of the theory remains weak and, in addition, extrapolation from laboratory studies to real-life situations is dangerous.

An evaluation of Eysenck's theory

- One of its most serious weaknesses is the failure to produce any convincing evidence that introverts condition more easily than extroverts. Conditionability is a vital part of the overall theory, because it points 'inwards' towards the biological (including genetic) basis of personality and 'outwards' towards the socialisation experiences of different individuals (behaviour always being the product of an interaction between the nervous system and the environment).
- Heim (1970) has criticised the EPI (and, by implication, the EPQ) because of its forced-choice ('yes/no') format. She argues that a few, simple yes/no questions can hardly be expected to do justice to the complexities of human personality, and she has criticised the lie scale for its lack of subtlety.
- Validation of the scales has involved the use of *criterion groups,* such as groups of neurotics, who tend to score at the extreme ends of the scale. But can we assume that the scale is 'valid' for the majority of people who lie somewhere in the middle? This needs to be empirically tested rather than simply assumed.
- According to Claridge & Davis (2003), Eysenck can take most of the credit for the *dimensional* approach to understanding psychological disorders. In using FA to identify the basic dimensions of *normal* personality, he always had in mind the need to describe and explain the *abnormal*. He believed that the various psychological disorders recognised in psychiatry actually define the *extremes* of his personality dimensions. (See Figure 42.4.)

His view was that disorders *aren't* diseases in the medical sense. Rather, they're *behavioural* disturbances, an exaggerated form of response patterns that characterise the personality dimensions. For example, anxiety neurotics are the clinical counterparts of individuals high on N and I.



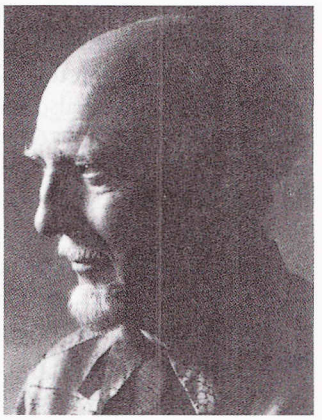


Figure 42.4 Eysenck's location of non-psychotic disorders in two dimensions of N/I-E (top) and psychotic disorders in two dimensions of P/I-E (bottom) (from Claridge & Davis, 2003)

While he was quite successful in mapping N onto *neurosis,* he was less successful in mapping P onto *psychosis.* The question is still open as to whether P has anything to do with psychosis at all. It seems to be more relevant to psychopathic and other antisocial behaviours than to psychotic disorders such as schizophrenia (Claridge & Davis, 2003).

- Shackleton & Fletcher (1984) have highlighted the vast amount of research Eysenck's theory has generated:

> Whilst the theory as it now stands is not adequate, some aspects of it, maybe even most, may well survive the test of time.

Indeed, E and N seem to have stood the test of time, in that they're both included in the 'big five' personality factors (see below).

Raymond B. Cattell (born 1905)

Cattell's trait theory

As we've already seen, Cattell's factors are first-order, oblique, source traits, which he believed to be the fundamental dimensions of personality, the underlying roots or causes of clusters of behaviour (surface traits). Whereas surface traits may correspond to common-sense ways of describing behaviour and may sometimes be measured by simple observation, they're actually the result of interactions among the source traits. Valid explanations of behaviour must concentrate on source traits as the structural factors which determine personality.

Cattell identified three sources of data relevant to personality: *L-data* (L for 'life'), *Q-data* (Q for 'questionnaire') and *T-data* (T for 'tests').

- *L-data* refer to ratings by observers. Cattell regarded these as the best source, but he also recognised that they're notoriously difficult to obtain; great skill and time are needed to make accurate ratings.
- *Q-data* refer to scores on personality questionnaires. His 16 factors (source traits) are measured by the widely used *Cattell 16 PF* (personality factor) *questionnaire,* which is intended for use with adults. As shown in Table 42.3, the first 12 factors are found in L-data and Q-data, while the last four (Q1–Q4) are based on Q-data only. There are versions of the 16 PF designed for children as young as four.

Cattell's scales aren't exclusively of the 'yes/no' variety (there may be three choices – yes/occasionally/no). Although intended mainly as a research instrument, the 16PF has been used in clinical work, as well as occupational selection and assessment. However, its validity as a diagnostic tool in a clinical setting has been seriously questioned.

- *T-data* refer to objective tests specially devised to measure personality. For example, the objective–analytic (O–A) test battery measures, amongst other things, GSR, reaction time, body sway and suggestibility. T-data are objective, primarily in the sense that the purpose of the test is concealed from the participant.

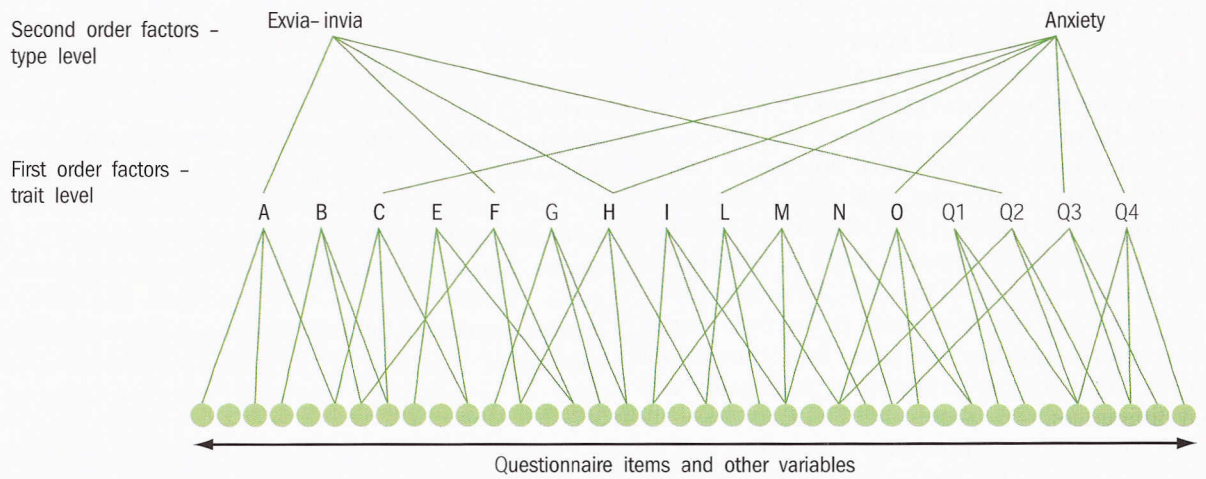

Figure 42.5 The hierarchical organisation of personality resulting from a second-order analysis of the first-order 'source traits' (after Cattell, 1965)

Differences between Cattell and Eysenck

- According to Cattell, some overlap between first-order (oblique) factors is to be expected. For example, an intelligent person (B-factor) is also likely to be shrewd and worldly (N-factor). Cattell also carried out a second-order FA of his 16 primary factors, which produced a number of surface traits. The two most important were *exvia–invia* and *anxiety*. These seem to correspond to Eysenck's E and N respectively (see Figure 42.5). Others included *radicalism* (aggressive and independent), *tenderminded-ness* (sensitivity, frustration and emotionality), and *superego* (conscientious, conforming and preserving).
- Cattell believes there's a fundamental *discontinuity* between normals and, say, schizophrenics; that is, there's a *qualitative* difference between them (and not merely a quantitative one, as Eysenck maintains). For example, Q-data used with psychiatric patients produce 12 factors which discriminate psychotics as a group (e.g. paranoia, suicidal disgust, schizophrenia and high general psychosis); they score highly on these factors compared with normals. A second-order FA of Q-data from psychiatric patients yields three factors, one of which resembles Eysenck's P.
- Cattell, much more than Eysenck, acknowledges how behaviour can fluctuate in response to situational factors. His definition of personality as that which 'determines behaviour in a defined situation and a defined mood' (Cattell, 1965) implies that behaviour is never totally determined by source traits. Although personality factors remain fairly stable over time, they constitute only one kind of variable influencing overt behaviour. Others include (a) *mood and state factors* (e.g. depression, arousal, anxiety, fatigue and intoxication); and (b) *motivational factors* (innate, biological drives and culturally acquired drives).

Single- and multi-trait theories, and the 'big five'

Eysenck's and Cattell's theories are examples of *multi-trait theories*. An influential *single-trait theory* is Rotter's (1966) locus of control (see Chapter 12). For a single-trait theory to be useful, it must identify a trait that determines a wide range of important behaviours (Hampson, 1995).

Multi-trait theories try to include all aspects of personality, and assume that individual differences can be described in terms of a particular profile on the same set of traits. According to Krahé (1992), despite its troubled history, 'the trait concept presents itself in remarkably good shape at the beginning of the '90s'. Since the 1980s, there's been a vast amount of research to discover a small but comprehensive number of basic trait dimensions which can account for the structure of personality and individual differences.

There's a growing consensus that personality can be adequately described by five broad constructs or factors, often referred to as the 'big five' (Costa & McCrae, 1992; Digman, 1990; Goldberg, 1993; McCrae & Costa, 1989).

Table 42.3 The 16 source traits measured by Cattell's 16 PF questionnaire (based on Cattell, 1965)

Description	Name of trait	Description
Warm-hearted, outgoing, easygoing, sociable	**A** Affectia vs Sizia	Reserved, cool, detached, aloof
Abstract thinker, intellectual interests [high score]	**B** Intelligence	Concrete thinker, practically minded [low score]
Emotionally stable, calm, mature	**C** Ego strength vs Dissatisfied emotionality	Emotionally unstable, easily upset, immature
Assertive, aggressive, dominant, competitive	**E** Dominance vs Submissiveness	Submissive, modest, mild, accommodating
Happy-go-lucky, enthusiastic	**F** Surgency vs Desurgency	Pessimistic, subdued, sober, cautious, serious
Persevering, conscientious moralistic [high score]	**G** Superego strength	Expedient, disregard for rules, law unto oneself [low score]
Adventurous, gregarious uninhibited	**H** Parmia vs Threctia	Shy, timid, diffident, inhibited
Tender-minded, sensitive, gentle, clinging	**I** Premsia vs Harria	Tough-minded, self-reliant, realistic, no-nonsense
Suspicious, jealous, self-opinionated	**L** Protension vs Alexia	Trusting, adaptable, easy to get along with
Unconventional, imaginative, bohemian	**M** Autia vs Praxernia	Conformist, conventional, influenced by external realities
Shrewd, calculating, worldly	**N** Shrewdness vs Naivety	Simple, unpretentious, lacking insight
Insecure, worrying, self-reproaching [high score]	**O** Guilt proneness	Self-assured, confident, complacent, spirited [low score]
Liberal, free-thinking	**Q1** Radicalism vs Conservatism	Conservative, traditional
Preference for own decisions	**Q2** Self-sufficiency vs Group dependence	Group dependent, a follower
Controlled, socially precise [high score]	**Q3** Self-sentiment Strength	Undisciplined, careless of social rules [low score]
Relaxed, composed [high score]	**Q4** Ergic tension	Overwrought, tense, frustrated [low score]

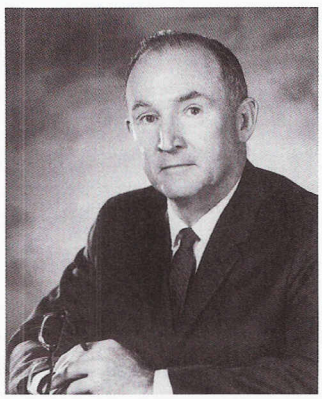
Table 42.4 The 'big five' personality factors

	Desirable traits	Undesirable traits
(I) Extroversion (corresponds to Eysenck's construct)	Outgoing, sociable, assertive	Introverted, reserved, passive
(II) Agreeableness	Kind, trusting, warm	Hostile, selfish, cold
(III) Conscientiousness	Organised, thorough, tidy	Careless, unreliable, sloppy
(IV) Emotional stability (or Neuroticism) (corresponds to Eysenck's construct).	Calm, even-tempered, imperturbable	Moody, temperamental, narrow
(V) Intellect/openness to experience	Imaginative, intelligent, creative	Shallow, unsophisticated, imperceptive

An evaluation of the 'big five'

- The 'big five' have their roots in attempts to seek the dimensions of personality in the natural language of personality description (John, 1990), and originated with Cattell's theory (Claridge & Davis, 2003).
- While different versions of the 'big five' have been proposed, the five-factor model has provided a unified framework for trait research (Costa & McCrae, 1993). It has mainly been concerned with personality description and structure, rather than underlying mechanisms and causes. But there's growing interest in possible *genetic* influences (Loehlin, 1992).
- Although Eysenck (1991) argues for his 'giant three' (E, N and P – a combination of factors II and III in the five-factor model), the differences seem quite trivial now compared with, say, the disagreement between Eysenck and Cattell's 16 source traits (Hampson, 1995). Not only do E and N appear in Table 42.4, but the negative pole of Agreeableness is similar to P, with overtones of aggressiveness, impulsiveness and general 'nastiness' (Claridge & Davis, 2003).
- Nevertheless, there remains the fundamental problem of the *meaning* of the factors that are extracted (Kline, 1993; Krahé, 1992). Ultimately, personality factors, however many, must be identified from their correlations with external criteria (Kline, 1993).
- According to Eysenck (1995), the system is still too new (except for E and N) for there to have been enough research to allow a proper evaluation. But Hampson (1999) believes that, at the end of the 1990s, the 'big five' remain pre-eminent as a description of normal personality.
- According to Moghaddam (2002), 'big five' theorists claim to have uncovered universal traits, with the implication that the central features of personality are relatively fixed from birth (but see Research Update 42.1). However, while he accepts that *the disposition to have dispositions* is *universal:*

> ... the particular dispositions one develops are to a large degree a result of interactions with the social and physical environment. The so-called Big Five have emerged through research with respondents from either Western societies or Westernized sections of other societies, typically students in modern universities modelled on Western universities.



Research update 42.1 The stability of personality across the lifespan

- According to Roberts & Delvecchio (2000), the consistency of personality increases from childhood to young adulthood, increases further still until about 30, then stabilises between 50 and 70.
- This was confirmed by Caspi (2000), who followed up a group of children from age three up to 21. Three-year-olds regarded as uncontrollable grew up to be impulsive, unreliable and antisocial, while those regarded as inhibited were more likely to grow up to be more depressed, unassertive, and to have fewer sources of social support.
- However, McCrae *et al.* (2000) suggest that some traits are more fluid than others. An international team of researchers looked at changes in the 'big five' between the ages of 14 and 30, in samples from Germany, the UK, Spain, the Czech Republic and Turkey. N, E and Openness to experience decreased over this period, but Agreeableness and Conscientiousness increased.

KELLY'S PERSONAL CONSTRUCT THEORY

Kelly's *personal construct theory* (PCT) is an idiographic approach, stressing the uniqueness of each individual. It's also a *phenomenological approach,* that is, a view of the world through a person's own eyes and not an observer's interpretation or analysis.

Man the scientist

George A. Kelly (1905–1966)

According to Kelly, we're all scientists in the sense that we put our own interpretation (or theories) on the world of events, and from these personal theories we produce

hypotheses (predictions about future events). Every time we act, we're putting our hypotheses to the test and, in this sense, behaviour is the independent variable – it is the experiment. Depending on the outcome, our hypotheses are either validated or not, and this will determine the nature of our subsequent behavioural experiments (Fransella, 1981).

Constructive alternativism

Although a real world of physical objects and events does exist, no one individual has the privilege of 'knowing' it: all we can do is place our personal constructs upon it. The better our constructs 'fit' the world generally, the better our control over our own, personal world will be. According to Kelly (1955), there's no way of getting 'behind' our interpretation of the world to check if it matches what the world is really like. All we have are our own interpretations, and so we necessarily see the world 'through goggles', which cannot be removed. However, these goggles or constructs aren't fixed once and for all. The person as scientist is constantly engaged in testing, checking, modifying, and revising his/her unique set of constructs.

The repertory grid technique

Box 42.6 Constructing a repertory grid (rep grid) (based on Kelly, 1955)

The basic method involves the following steps.

- Write a list of the most important people in your life (*elements*).
- Choose *three* of these elements.
- Ask yourself, in what ways are two of these alike and different from the third?

The descriptions given (e.g. 'My mother and girlfriend are affectionate, my father is not') constitute a *construct,* which is expressed in a *bipolar way* ('affectionate–not affectionate').

- This construct is applied to all the remaining elements. Remember, constructs are bipolar opposites (either affectionate or not affectionate).
- Then another set of three elements is selected, and the whole process is repeated. It continues until either you've produced all the constructs you can (which is usually no more than 25 with one set of elements), or until a sufficient number has been produced as judged by the investigator.

All this information can be collated in the form of a grid, with the elements across the top and the constructs down the side, and a tick or cross indicating which pole of the construct is applicable (for example, a tick indicates 'affectionate' and a cross indicates 'not affectionate': see Table 42.5).

Table 42.5 Example of a rep grid

Constructs	Elements						
	Mother	Father	Brother	Sister	Boyfriend	Girlfriend	Psychology lecturer etc.
Affectionate (✓) Non-affectionate (×)	✓	×	×	✓	×	✓	✓
Intelligent (✓) Unintelligent (×)							
Sense of humour (✓) No sense of humour (×)							
etc.							

ASK YOURSELF...

- Have a go at constructing your own repertory grid.

The *repertory grid test* is an attempt to help individuals discover the fundamental constructs they use for perceiving and relating to others. It's used as a major research instrument, is very flexible, and can be used in different ways. It can be factor-analysed, which often reveals that many constructs overlap (they mean more or less the same thing). Probably between three and six major constructs cover most people's construct system.

The rep grid can be used *nomothetically,* as Bannister and Fransella have done with thought-disordered schizophrenics. Their grid test of thought disorder (Bannister & Fransella, 1967) contains standardised elements and constructs (supplied by the researcher). It has been standardised on large numbers of similar patients, so that an individual score can be compared with group norms. However, this is probably rather far removed from how Kelly intended the technique to be used.

The rep grid has also been used to study how patients participating in group psychotherapy change their perception of each other (and themselves) during the period of therapy: the group members themselves are the elements and a number of constructs are supplied (Fransella, 1970). Fransella (1972) has used this method extensively with people being treated for severe stuttering.

However, its uses aren't confined to clinical situations. Elements needn't be people at all, but can be occupations, religions, cars, and so on. Shackleton & Fletcher (1984) argue that the rep grid stands on its own as a technique – you don't have to believe in Kelly's PCT in order to use it.

An evaluation of PCT

- Bannister & Fransella (1980) and Fransella (1981) point out that PCT is deliberately stated in very abstract terms to avoid the limitations of a particular time and culture. It's an attempt to redefine psychology as a psychology of people and is 'content free'. As we noted earlier, PCT isn't so much a personality theory, more a total psychology. Kelly isn't concerned with separate subdivisions of psychology as dealt with in most textbooks. For example, the traditional concept of *motivation* can be dispensed with. We don't need concepts like drives, needs, or psychic energy to explain what makes people 'get up and go' – man is a form of motion and a basic assumption about life is that 'it goes on':

  > It isn't that something makes you go on, the going on is the thing itself ... (Kelly, 1962).

- However, he implicitly assumes that we all seek a sense of order and predictability in our dealings with the external world – the overriding goal of anticipating the future represents a basic form of motivation. We achieve this through behaving much like a research scientist. 'The scientist's ultimate aim is to predict and control' (see Chapter 3).
- Various aspects of *emotion* are dealt with in terms of how an individual's construct system is organised and how it changes. For example, 'anxiety' is the awareness that what you're confronted with isn't within the framework of your existing construct system – you don't know how to construe it. For some, this approach is far too cognitive and rational, leaving the subjective experience (the 'gut feeling') that we call anxiety out of the picture (see Chapter 44).
- Peck & Whitlow (1975) believe that Kelly trivialises important aspects of behaviour, including learning, emotion and motivation, and neglects situational influences on behaviour. PCT appears to place the person in an 'empty world'. However, they conclude by saying that:

  > Personal construct theory constitutes a brave and imaginative attempt to create a comprehensive, cognitive, theory of personality.

HUMANISTIC THEORIES

Humanistic theories (and Kelly's PCT) have their philosophical roots in *phenomenology* and *existentialism,* and some would say they're more 'philosophical' than 'psychological'. They're concerned with characteristics that are distinctively and uniquely human, in particular experience, uniqueness, meaning, freedom, and choice. We have first-hand experience of ourselves as people, and Rogers' theory in particular is centred around the self-concept.

What Rogers and Maslow have in common is their positive evaluation of human nature, a belief in the individual's potential for personal growth (*self-actualisation*). But while Maslow's theory is commonly referred to as a 'psychology of being' (self-actualisation is an end in itself and lies at the peak of his *hierarchy of needs:* see Chapter 9), Rogers' is a 'psychology of becoming' (it's the *process* of becoming a 'fully functioning person' that's of major importance and interest).

Rogers' self theory

Rogers (like Maslow) rejected the deterministic approach of psychoanalytic theory (see below) and behaviourism (see Chapter 2). Instead, humanistic theorists see behaviour as a response to the individual's perception/interpretation of external stimuli. As no-one else can know how we perceive, we're the best experts on understanding our own behaviour. Rogers also sees human nature in a very positive and optimistic light: 'There is no beast in man; there is only man in man'.

The self

The *self* is an 'organised, consistent set of perceptions and beliefs about oneself'. It includes a person's awareness of 'what they are and what they can do', influencing both their perception of the world and their behaviour. We evaluate every experience in terms of self, and most human behaviour can be understood as an attempt to maintain consistency between our self-image and our actions (see Chapter 33).

However, this consistency isn't always achieved and our self-image (and related self-esteem) may differ quite radically from our actual behaviour and from how others see us. For example, a person may be highly successful and respected by others, and yet regard him/herself as a failure! This illustrates what Rogers calls *incongruence.* Because incongruent experiences, feelings, actions, and so on conflict with our (conscious) self-image (and because we prefer to act and feel in ways that are consistent with our self-image), they can be threatening. Consequently, we may deny them access to awareness (they may remain *unsymbolised*) through actual denial, distortion or blocking.

These *defence mechanisms* prevent the self from growing and changing, and widen the gulf between our self-image and reality (our actual behaviour or our true feelings). As the self-image becomes more and more unrealistic, so the incongruent person becomes more and more confused, vulnerable, dissatisfied and, eventually, seriously maladjusted. By contrast, the self-image of the congruent person is flexible and changes realistically as new experiences occur. When your self-image matches what you really think and feel and do, you're in the best position to self-actualise.

Box 42.7 Two examples of a rigid and inflexible self-image

- Suppose that a young man's self-image requires that every woman he meets will find him irresistible and fall head-over-heels in love with him. He meets a woman whom he finds attractive, but she shows no interest in him (this represents incongruence between his self-image and his experience). How does he deal with the threat this represents for him? He might say, 'She's just playing hard to get' or 'She has no taste' or 'She must be crazy – thank goodness I found out before she fell hopelessly in love with me'.
- At the opposite extreme is a young man who believes he's totally unattractive to women. If an attractive woman shows an interest in him, this will produce incongruence and hence threat, and he might deal with it by rationalising: 'She's just feeling sorry for me', or he might deliberately do something to sabotage the relationship and so remove the threat.

Development of the self-concept

Many of Rogers' therapeutic clients seemed to have learned during childhood that in order to obtain the love and acceptance of *significant others* (particularly parents), they have to feel and act in distorted or dishonest ways (*conditional positive regard*).

To maintain conditional positive regard, we develop *conditions of worth* (those conditions under which positive regard will be forthcoming) which become internalised. We perceive and are aware of those experiences that coincide with the conditions of worth, but distort or deny those that don't. This denial and distortion lead to a distinction between the *organism* (the whole of our possible experience, everything we do, feel, and think) and the *self* (the recognised, accepted, and acknowledged part of our experience). Ideally, the two would coincide, but for most of us they don't.

Corresponding to the need for positive regard is the need for *positive self-regard* (thinking of ourselves as good, lovable and worthy). To experience positive self-regard, our behaviour and experience must match our conditions of worth – but this can produce incongruence through the denial of our true thoughts and feelings. Since the need for positive regard and positive self-regard is so strong, these conditions of worth can supersede the values associated with self-actualisation. Consequently, we come to behave, think and feel in particular ways because others want us to, and many adult adjustment problems are bound up with an attempt to live by other people's standards instead of one's own.

ASK YOURSELF...

- Can you think of any examples of where you have lived – or currently do live – by other people's standards?
- Is this (at least in part) an inevitable part of being a dependent child?
- Is living by your own standards a way of defining psychological adulthood? (See Chapter 38.)

The therapist in Rogers' *client-centred therapy* provides the client with *unconditional positive regard*. The therapist creates an atmosphere of total acceptance and non-judgemental support, regardless of what the client says or does. In this way, the client in turn comes to accept certain feelings and thoughts as his/her own, instead of denying, distorting, and disowning them. Finally, positive self-regard is no longer dependent upon conditions of worth (see Chapter 45).

PSYCHODYNAMIC THEORIES

As we saw in Chapter 2, *psychodynamic* implies the active forces within the personality that motivate behaviour, in particular the unconscious conflict between the id, ego and superego. Freud's was the first of this kind of theory and all psychodynamic theories stem, more or less directly, from Freud's *psychoanalytic theory.*

ASK YOURSELF...

- What do you already know about Freud's ideas?
- Psychoanalytic theory applies to motivation (Chapter 9), forgetting (Chapter 21), prejudice (Chapter 25), aggression (Chapter 29) and many aspects of development (see Chapters 35–38).

Freud's psychoanalytic theory

Freud believed that conflict within the personality is unavoidable, because the ego is being 'pulled' in two opposing directions by the id and the superego. The ego's solution comes in the form of three forms of compromise, namely *dreams, neurotic symptoms* and *defence mechanisms.*

Dreams

'A dream is a [disguised] fulfilment of a [suppressed or repressed] wish' (Freud, 1900; 1976a). It represents a compromise between forbidden urges and their expression. What we dream about and are conscious of upon waking is called the *manifest content,* while the dream's meaning (the wish being fulfilled) is the *latent content.* The manifest content is often the product of the weaving together of certain fragments from that day's events (*day residues*) and the forbidden wish. It often appears disjointed, fragmentary, and sometimes bizarre and nonsensical. *Dream interpretation* (a major technique involved in psychoanalysis) aims to make sense of the manifest content by 'translating' it into the underlying wish fulfilment.

CASE STUDY 42.1 An Oedipal dream reported by one of Freud's patients (from *The Interpretation of Dreams*, 1900; 1976a)

A 'typical example of a disguised Oedipus dream' is that of a man who dreamt that he had a secret liaison with a lady whom someone else wanted to marry. He was worried in case this other man might discover the liaison and the proposed marriage come to nothing. He, therefore, behaved in a very affectionate way to the man. He embraced him and kissed him.

ASK YOURSELF...

- How do you think Freud interpreted this dream?

The Nightmare (Fuseli)

Dreams come into being through *dream work* (controlled by the ego), which converts the underlying (latent) wish into the manifest content. It involves *displacement, condensation* and *concrete representation*.

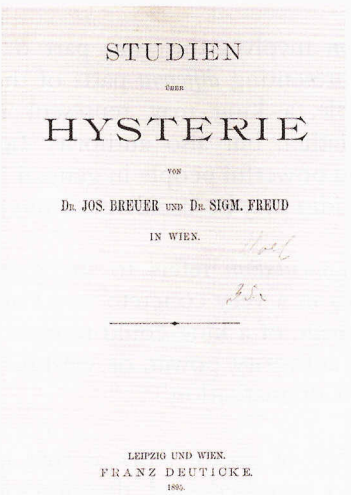
- *Displacement* refers to the substitution of the real target of the dreamer's feelings by a person or object that then becomes the target for those feelings. The substitute is symbolically (unconsciously) linked to the true target, as in the example of one of Freud's patients who dreamed of strangling a little white dog which represented her sister-in-law, who had a very pale complexion and whom the dreamer had previously called 'a dog who bites' (Stevens, 1995). This is a crucial part of the *disguise* that conceals from the dreamer the true meaning of the dream.

The sister-in-law/dog example shows how certain symbols will be peculiar to individual dreamers. But many dream symbols have a conventional meaning within a culture, particularly those that represent the penis (e.g. snakes, trees, trains, daggers, umbrellas), the vagina (e.g. small boxes, cupboards, ships, and other vessels), and sexual intercourse (e.g. climbing ladders or stairs and entering tunnels).

A symbol of sexual intercourse – or simply a train entering a tunnel?

- *Condensation* involves the *same* part of the manifest content representing *different* parts of the latent wish. For example, a king may represent not only the dreamer's father, but also authority figures or very wealthy and powerful people in general. So, more than one dream idea may be 'condensed' into a single manifest image.
- *Concrete representation* refers to the expression of an abstract idea in a very concrete way. For example, the concrete image of a king could represent the abstract notions of authority, power, or wealth. This is sometimes called 'dramatisation'.

The importance of dream work is that it permits the expression of a repressed (and, therefore, forbidden and disturbing) wish, and at the same time allows the dreamer to go on sleeping. The compromise represented by dreaming takes the form of disguising the true nature of the dream (i.e. wish fulfilment), for if it weren't disguised, the dreamer would wake up in a state of shock and distress. Hence, 'the dream is the guardian of sleep'.



Dream interpretation is also what Freud called the 'royal road to the unconscious'. Reversing the dream work, and unravelling the wish from the manifest content, can provide invaluable information about the unconscious mind in general, and about the dreamer's in particular.

Neurotic symptoms

Like dreams, neurotic symptoms are essentially the expression of a repressed wish (or memory) that's become

disguised in very similar ways to dream work. The symptom may in some way symbolise the wish it's linked to, as in a patient who suffered from hysterical hand-twitching, which was related to her memories of being badly frightened while playing the piano (*displacement*). This same patient's hand-twitching was traced to two other memories (receiving a disciplinary strapping on the hands as a schoolgirl, and being forced to massage the back of a detested uncle: *condensation*). The symptom is often something 'physical', while the underlying cause is something 'mental' (*concrete representation*).

Most of Freud's patients were suffering from 'hysterical conversion neurosis' (or 'somatoform' disorders in current terminology): emotional energy is converted into a bodily form (such as paralysis, blindness, deafness, headaches and a whole variety of other 'physical' symptoms: see Chapter 44). The symptom deflects the patient's attention (and that of others) away from the repressed material: it's acceptable to consult a doctor about the symptom, but not about the unconscious wish. Freud & Breuer (1895) called these underlying wishes and memories *pathogenic* ('disease-producing') ideas, and Freud later concluded that all symptoms are caused by pathogenic ideas of a sexual nature (although not every dream).

Defence mechanisms

The *ego defence mechanisms* are, by definition, unconscious, and this is partly what makes them effective. They involve some degree of self-deception which, in turn, is related to their distortion of 'reality' (both internal and external). This prevents us from being overwhelmed by temporary threats or traumas, and can provide 'breathing space' in which to come to terms with conflict or find alternative ways of coping. As short-term measures, they're advantageous, necessary, and 'normal', but as long-term solutions to life's problems they're usually regarded as unhealthy and undesirable. Many of the defences described in Table 42.6 (and others) were originally proposed or implied by Freud and later elaborated by his daughter, Anna Freud (1936).

ASK YOURSELF...

- How are these defence mechanisms related to the *coping mechanisms* described by Grasha (1983) in relation to *stress?* (See Chapter 12.)

Levels of consciousness

According to Freud, thoughts, memories, and other psychic material could operate at one of three levels: *conscious, preconscious,* and *unconscious.* What we're consciously aware of at any one time represents the mere tip of an iceberg – most of our thoughts and ideas are either not accessible at that moment (preconscious) or are totally inaccessible (unconscious), unless special techniques such as free association and dream interpretation are used (see Chapter 45).

The ego represents the conscious part of the mind, together with some aspects of the superego (namely, those moral rules and values we're able to express in words: see Chapter 35). The unconscious comprises: (a) id impulses; (b) all repressed material; (c) the unconscious part of the ego (the part involved in dream work, neurotic symptoms, and defence mechanisms); and (d) part of the superego (for example, the vague feelings of guilt or shame which are difficult to account for). Freud depicted the unconscious as a *dynamic force* and not a mere 'dustbin' for all those thoughts and feelings which are too weak to force themselves into awareness. This is best illustrated by the process of repression (Thomas, 1985).

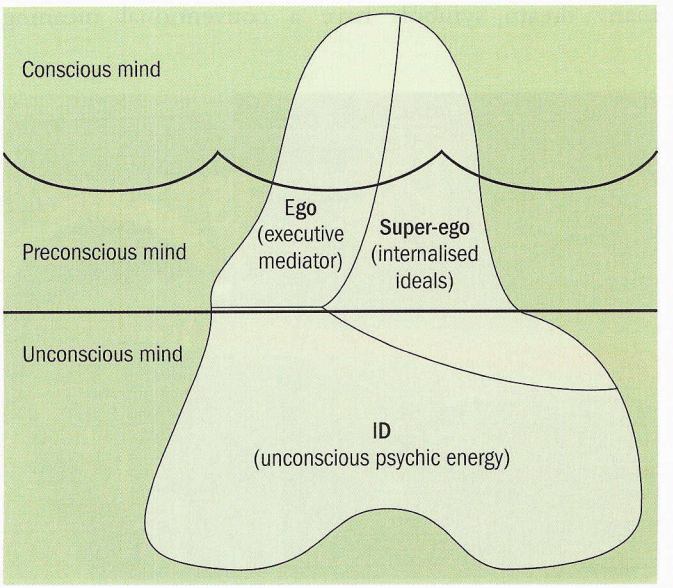

Figure 42.6 The components of the personality in relation to three levels of consciousness

Jack Nicholson, displacing in *As Good As It Gets*

Psychic determinism

Much of our behaviour (and our thoughts and feelings) has *multiple* causes, some conscious, some unconscious. Freud called this *overdetermination*. By definition, we know only about the conscious causes, which we normally take to be the reasons for our actions. But if some of the causes are also unconscious, then the reasons we give for our behaviour can never tell the whole story (and the unconscious causes may be the more important). This means that we don't know ourselves as well as we'd like, or as well as we think we do ('irrational man').

Overdetermination is one aspect of *psychic determinism*, the view that all behaviour is purposive or goal-directed and that everything we do, think and feel has a cause. It follows that so-called 'accidents' (things which 'just happen') do have a cause after all – and the cause may actually turn out to be the 'victim'. For instance, the 'accident-prone' person isn't an unfortunate victim of circumstances, but is unconsciously bringing the accidents about – perhaps in an attempt to punish him/herself in some way. While not denying the existence of events which lie beyond people's control, Freud believed that it's more common for an 'accident' to be the consequence of our own, unconscious wishes and motives.

The psychopathology of everyday life

Another important way in which our everyday behaviour provides us with glimpses of the unconscious is what Freud called *Fehlleistungen* ('faulty achievements': Bettelheim, 1985), the all too common slips of the tongue ('Freudian slips'), slips of the pen, forgetting things (including words and people's names), leaving

Table 42.6 Some major ego defence mechanisms

Name of defence mechanism	Description	Example(s)
Repression	Forcing a threatening or distressing memory/feeling/wish out of consciousness and making it unconscious	A five-year-old child repressing its incestuous desire for the opposite-sex parent (see Chapter 35)
Displacement	Transferring our feelings from their true target onto a harmless, substitute target (e.g. 'kicking the cat')	Frustration caused by problems at work expressed as domestic violence (see Chapter 29); phobias (see Chapter 44)
Denial	Failing/refusing to acknowledge/perceive some aspect of reality	Refusing to accept that you have a serious illness, or that your partner is going off you (see Chapter 39)
Rationalisation	Finding an acceptable excuse (a 'cover story') for some really quite unacceptable behaviour/situation	'Being cruel to be kind'; 'I only did it because I love you' (see Chapter 24)
Reaction-formation	Consciously feeling/thinking the opposite of your true (unconscious) feelings/thoughts	Being considerate/polite to someone you strongly dislike – even going out of your way to be nice to them
Sublimation	A form of displacement in which a (socially positive) substitute activity is found for expressing some unacceptable impulse	Playing sport to redirect aggressive urges (see Chapter 29)
Identification	Incorporating/introjecting another person into one's own personality – making them part of oneself	Identification with the aggressor (boys)/anaclitic identification (girls) (see Chapter 35)
Projection	Displacing your own unacceptable feelings/characteristics on to someone else	'I hate you' becomes (through reversal of subject/object) 'you hate me' (see Chapter 44)
Regression	Reverting to behaviour characteristic of an earlier stage of development	Losing your temper, comfort eating, sleeping more when depressed (see Chapter 44)
Isolation	Separating contradictory thoughts/feelings into 'logic-tight' compartments	Talking about some traumatic experience without any display of emotion – or even giggling about it (see Chapter 44)

things behind and 'accidents'. Freud's translators used the term *parapraxes.*

ASK YOURSELF...

- Try and think of some examples of Freudian slips that have happened to you or that you've witnessed.
- How can you explain them?

Box 42.8 Some examples of parapraxes ('Freudian slips') (from *The Psychopathology of Everyday Life,* 1901, 1976b)

1. A patient consulted me for the first time and from her history it became apparent that the cause of her nervousness was largely an unhappy married life. Without any encouragement she went into details about her marital troubles. She had not lived with her husband for about six months and she saw him last at the theatre, when she saw the play *Officer 606*. I called her attention to the mistake and she immediately corrected herself, saying that she meant to say *Officer 666* (the name of a recent popular play). I decided to find out the reason for the mistake, and as the patient came to me for analytic treatment, I discovered that the immediate cause of the rupture between herself and her husband was the disease which is treated by '606' [i.e. venereal disease].
2. I was to give a lecture to a woman. Her husband, upon whose request this was done, stood behind the door listening. At the end of my sermonising, which had made a visible impression, I said, 'Goodbye, sir!' To the experienced person I thus betrayed the fact that the words were directed towards the husband; that I had spoken to oblige him.
3. While writing a prescription for a woman who was especially weighted down by the financial burden of the treatment, I was interested to hear her say suddenly, 'Please do not give me big bills, because I cannot swallow them'. Of course she meant to say pills.

An evaluation of Freud's theory

Empirical studies

There have been literally thousands of empirical studies of various aspects of Freud's theory. Two of the major reviews of this research have been carried out by Kline (1972, 1982) and Fisher & Greenberg (1977). They conclude that psychoanalytic theory cannot be accepted or rejected as a total package. As Fisher and Greenberg say:

> It is a complex structure consisting of many parts, some of which should be accepted, others rejected and the rest at least partially reshaped.

Three basic kinds of study have been carried out:

- *validational studies,* which try to test directly various parts of the theory, mainly in the laboratory
- those that try to investigate some of the *underlying mechanisms* involved, but that aren't direct tests of the theory (again mainly laboratory experiments)
- studies of the *effects of psychoanalysis* as therapy (see Chapter 45).

Fonagy (1981) asks whether it's conceivable that laboratory studies could 're-create' the clinical concepts and experience that Freud describes and, therefore, questions the usefulness of validational studies. He also queries the relevance of studies of treatment effectiveness as a way of 'testing' the theory – they're equivalent to the relevance of the effectiveness of aspirin to a theory of headaches!

Many validational studies have been concerned with Freud's theory of personality types, especially the oral and anal (see Chapter 35) and defence mechanisms, including repression (see Chapters 12 and 21). Fonagy (1981) believes that most relevant are studies which go beyond trying to replicate clinical phenomena, and which instead attempt to identify basic mechanisms or processes which may underlie unconscious phenomena.

Is the theory scientific?

Popper's criticism that Freud's theory is *unfalsifiable* and, therefore, unscientific, is discussed in Chapter 2. However, it would be a serious mistake to regard *reaction formation* (the example used by Popper) as typifying Freudian theory, and the sheer volume of research suggests that Freudian theory cannot be dismissed as lightly as Popper and Eysenck would like on the grounds of it being 'unscientific'. According to Kline (1989), the view adopted by almost all experimental psychologists involved in the study of Freud's theory is that it should be seen as a collection of hypotheses. As Fisher & Greenberg (1977) argue, some of these hypotheses will turn out to be true, others false, when put to Popper's test of falsifiability.

Some hypotheses are undoubtedly more critical to the overall theory than others. For example, if no evidence could be found for repression, this would alter considerably the nature of psychoanalysis. But if it was found that the Oedipus complex was more pronounced in small as opposed to large families, the theory wouldn't be radically affected (Kline, 1989).

How valid is the case study method?

Although Freud often states or implies that his theories have been derived from his observations of his patients, he left us no direct record of the original data. He deliberately made no notes during therapy sessions, since this might interfere with the therapeutic relationship (see Chapter 45). He wrote them up several hours later, so that his case studies are *reconstructions* of what happened.

He also reported on very few patients; only 12 are reported in depth, and in some of these the details are incomplete (Stevens, 1995).

The case study relies on the reconstruction of childhood events, and, as used by Freud, is generally considered to be the least scientific of all empirical methods used by psychologists. It's open to many types of distortion and uncontrolled influences.

Box 42.9 The limitations of the case study method

- Fisher & Greenberg (1977) point out Freud's tendency to select or emphasise material which supported particular interpretations. This form of bias is blatantly obvious in the case of Little Hans. As we saw in Chapter 35, Freud (1909) recognised that there was a problem of objectivity, because it was Little Hans' father actually conducting the psychoanalysis. But he goes on to say that this case was no different from the analysis of adults:

  For a psychoanalysis is not an impartial scientific investigation, but a therapeutic measure. Its essence is not to prove anything but merely to alter something.

- Freud seems to be digging a very large hole for himself! According to Storr (1987), the majority of psychoanalytic hypotheses are based on observations made in the course of psychoanalytic treatment, which cannot be regarded as a scientific procedure. Such observations are inevitably contaminated by the subjective experience and prejudice of the observer, however detached s/he tries to be, and so they cannot be regarded in the same light as observations made during, say, a chemistry or physics experiment.

How representative were Freud's patients?

One of the standard criticisms made of Freud's database is that his patients were mainly wealthy, middle-class Jewish females, living in Vienna at the turn of the century. This makes them highly unrepresentative of the population to whom his theories were generalised. If these people were also neurotic, how can we be sure that what Freud discovered about them is true of normal individuals? However, Freud regarded neurosis as continuous with normal behaviour, that is, neurotics are suffering only from *more extreme* versions of problems experienced by all of us (see Chapter 43).

More serious, perhaps, is the criticism that Freud studied only adults (with the very dubious exception of Little Hans), and yet he put forward a theory of personality development. How many steps removed were his data from his theory? According to Thomas (1985), the analyst interprets, through his or her theoretical 'lens', ostensibly symbolic material derived from the reported dreams, memories, and so on of neurotics about apparent experiences stemming from their childhood one or more decades earlier. However, this in itself doesn't invalidate the theory; it merely makes the study of children all the more necessary.

Reification

Several writers have criticised terms like the id, ego and superego as bad metaphors. They don't correspond to any aspect of psychology or neurophysiology, and they encourage *reification,* that is, treating metaphorical terms as if they were 'things' or entities.

However, Bettelheim (1985) points out that much of Freud's terminology was mistranslated, and this has led to a misrepresentation of those parts of his theory. For example, Freud used the German terms *das Es* ('the it'), *das Ich* ('the I') and *das Über-Ich* ('the over-I'), which were intended to capture how the individual relates to different aspects of the self. The Latin terms *id, ego,* and *superego* tend to depersonalise these, and give the impression that there are three separate 'selves' which we all possess! The Latin words (chosen by his American translator to give them greater scientific credibility) turn the concepts into cold technical terms which arouse no personal associations. Whereas 'the I' can only be studied from the inside (through introspection), the 'ego' can be studied from the outside (as behaviour). In translation, Freud's 'soul' became scientific psychology's 'psyche' or 'personality' (Bettelheim, 1985).

The nature of Freudian theory

As noted in Chapter 2, Freud's theory has great *hermeneutic strength*, that is, it provides methods and concepts which enable us to interpret and 'unpack' underlying meanings (Stevens, 1995). Stevens claims that:

> Although Freud wanted to create a nomothetic theory ... in effect he finished up with a set of 'hermeneutic tools' – concepts and techniques that help us to interpret underlying meanings ...

There's no doubting the tremendous impact that Freud has had, both within psychology and outside. The fertility of psychoanalytic theory, in terms of the debate, research, and theorising it has generated, makes it one of the richest in the whole of psychology. According to Kline (1989):

> ... Freudian theory is still a powerful intellectual force. To claim that it is dead, as do many experimental psychologists – at least by implication for it rarely influences their thinking – must be either ignorance or wishful thinking.

Jung's analytical psychology

Structure of the personality and levels of consciousness

For Jung, the person is a whole almost from the moment of birth. Personality isn't acquired piece by piece (the 'jigsaw' concept) through learning and experience, but is already there. So, instead of striving to achieve wholeness,

our aim in life is to maintain it and to prevent the splitting or *dissociation* of the psyche into separate and conflicting parts. Jung saw the role of therapy as helping the patient recover this lost wholeness, and to strengthen the psyche so as to resist future dissociation.

The psyche comprises three major, interacting levels:

1. consciousness
2. the personal unconscious
3. the collective unconscious.

The distinction between 2 and 3 represents one of the major differences between Jung and Freud.

Consciousness

This is the only part of the mind known directly by the individual. It appears early in life through the operation of four basic functions: *thinking, feeling, sensing,* and *intuiting.* In addition, there are two attitudes which determine the orientation of the conscious mind: *extroversion* and *introversion.*

Box 42.10 Extroversion and introversion, Jungian style

- The extrovert's libido (Jung's term for psychic energy as a whole or life-force) is directed outwards towards the objective world of physical objects, people, customs and conventions, social institutions, and so on. Extroverts are preoccupied with interpersonal relationships, and are generally more active and outgoing.
- The introvert's libido is directed inwards towards the subjective world of thoughts and feelings, and they're preoccupied with intrapersonal matters, are introspective and withdrawn, and may be seen by others as aloof, reserved, and antisocial.
- Jung believed that a person is predominantly one or the other throughout life, although there may be occasional inconsistencies in different situations. So, for Jung, extroversion–introversion represents a typology of the 'either/or' variety. By contrast, as we saw above, Eysenck's 'adoption' of Jung's terms took the form of personality dimensions, with extreme extroversion at one end and extreme introversion at the other.

The development of consciousness is also the beginning of *individuation,* the process by which a person becomes psychologically 'in-dividual' (a separate, indivisible unit or whole). From this process emerges the ego, which refers to how the conscious mind is organised. It plays the essential role of 'gatekeeper to consciousness', selecting important sensations, feelings, and ideas, and allowing them through into conscious awareness (much as Freud's preconscious does). This prevents us from becoming overwhelmed by the mass of stimulation going on around (and inside) us. The ego provides a sense of identity and continuity, and is the central core of the personality.

The personal unconscious

The Freudian unconscious, in Jung's terms, is predominantly 'personal', that is, composed of the individual's particular and unique experiences which have been made unconscious through repression. For Jung, repressed material represents only one kind of unconscious content. The personal unconscious also includes things we've forgotten, as well as all those things we think of as being 'stored in memory' and which could become accessible by conscious recall (see Chapter 17).

Associated groups of feelings, thoughts and memories may cluster together to form a *complex,* a quite autonomous and powerful 'mini-personality' within the total psyche. The term is commonly used in everyday language, together with synonyms such as 'hang-up' (Hall & Nordby, 1973), and Freud's Oedipus complex illustrates this constellation of thoughts and feelings. Complexes often prevent complete individuation from taking place, and one aim of therapy is to free the patient from the grip of such complexes. In looking for the origin of complexes, Jung eventually turned to the collective unconscious.

The collective unconscious

This part of Jung's theory sets him apart from Freud probably more than any other. While Freud's id is part of each individual's personal unconscious and represents our biological inheritance, Jung believes that the mind (through the brain) has inherited characteristics which determine how a person will react to life experiences, and what type of experiences these will be. Unlike Freud, Jung attached relatively little importance to our individual past in relation to the personal unconscious, but saw the evolutionary history of human beings as a species as being all-important in relation to the *collective* (or *racial*) *unconscious.*

The collective unconscious can be thought of as a reservoir of *latent* (or *primordial*) *images.* These relate to the 'first' or 'original' development of the psyche, stemming from our ancestral past, human, pre-human, and animal (Hall & Nordby, 1973). These images are predispositions or potentialities for experiencing and responding to the world in the same way that our ancestors did. For example, we don't have to learn to fear the dark or snakes through direct experience, because we're naturally predisposed to develop such fears through the inheritance of our ancestors' fears.

These primordial images are also known as *archetypes* (a prototype or 'original model or pattern'). These are more like a photographic negative (which has to be developed through experience) than an already developed and clearly recognisable photograph (Hall & Nordby, 1973); they are 'forms without content', potential ways of perceiving, feeling and acting. Jung identified a large number of archetypes, including birth, rebirth, death, power, magic, the hero, the child, the trickster, God, the

demon, the wise old man, earth mother, and the giant. He gave special attention to the *persona,* the *anima/animus,* the *shadow,* and the *self.*

ASK YOURSELF...

- Is there any evidence from the study of phobias that supports Jung's account of the collective unconscious? (See Box 44.2, page 778.)

A demon from the Temple of the Emerald Buddha, Bangkok, Thailand

Box 42.11 The four major archetypes of the collective unconscious

The persona ('mask'): This is the outward face we present to the world, both revealing and concealing the real self. It allows us to play our part in social interaction, and to be accepted by others. It's the 'packaging' of the ego, the ego's PR man or woman, a kind of cloak between the ego and the objective world. It's very similar to the notion of a social role, which refers to the expectations and obligations associated with a particular social position. Jung describes it as the 'conformity' archetype.

Anima/animus: This refers to the unconscious mirror image of our conscious ('official') sex. If we're male, our anima is our unconscious female side, and if we're female, our animus is our unconscious male side. We all have qualities of the opposite sex – both biologically and psychologically – and in a well-adjusted person both sides must be allowed to express themselves in thought and behaviour.

The anima prefers all things vain, helpless, uncertain, and unintentional; the animus prefers the heroic, the intellectual, the artistic, and athletic. Jung believed that repression of the anima/animus is very common in western culture, where the persona predominates.

The shadow: This contains more of our basic animal nature than any other archetype. Like Freud's id, it must be kept in check if we're to live in society. But this isn't achieved easily, and is always at the expense of our creativity and spontaneity, depth of feeling and insight. So, the shadow represents the source of our creative impulses, but also of our destructive urges. When the ego and shadow work harmoniously, the person is full of energy, both mentally and physically. The shadow of the highly creative person may occasionally overwhelm the ego, causing temporary insanity (confirming the popular belief that genius is akin to madness: see Chapter 44).

The self: This is the central archetype ('the archetype of archetypes'), which unites the personality, giving it a sense of 'oneness' and firmness. The ultimate aim of every personality is to achieve a state of selfhood and individuation (similar to self-actualisation). This is a lifelong process, attained by very few individuals, Jesus and Buddha being notable exceptions. It is commonly represented as a *mandala,* an age-old symbol of wholeness and totality, found all over the world.

A mandala, the *Buddha of the Golden Wheel* (14th century)

According to Brown (1961), there are three major sources of evidence for the collective unconscious:

1. the 'extraordinary' similarity of themes in the mythologies of various cultures
2. the recurring appearance, in therapy, of symbols which have become divorced from any of the patient's personal experiences, and which become more and more like the primitive and universal symbols found in myths and legends
3. the content of fantasies of psychotics (especially schizophrenics), which are full of themes such as death and rebirth (similar to those found in mythology).

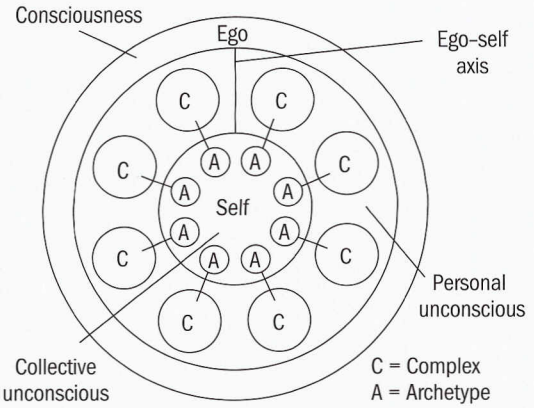

Figure 42.7 Schematic diagram of Jung's model of the psyche (based on Stevens, 1990)

Brown argues that members of all cultures share certain common experiences, and so it's not surprising that they dream or create myths about archetypal themes.

Dream theory

Jung shared Freud's belief that dreams are the 'royal road to the unconscious', but he disagreed with Freud that all dreams are wish fulfilments. Rather, Jung saw dreams as an important way of attaining self-knowledge which, in turn (together with religious or spiritual experiences), is a path to achieving individuation.

The great function of dreams is to re-establish 'the total psychic equilibrium' and they're just as likely to point to the future (by suggesting a solution to a conflict, for example) as to the past. He also believed that Freud's 'disguise' was far too elaborate, preferring to take dreams at face value. Dream symbols don't have a fixed meaning (as they very largely did for Freud), and Jung also advocated the study of *dream series,* that is, several dreams by the same individual recorded over a period of time.

Neurosis and therapy

Repression plays very little part in Jung's theory of neurosis. More important is the conflict between different parts of the personality which have developed unequally. Jungian therapy is much more concerned with future goals than past history, and the patient's present situation is the key to neurosis. Therapy aims to bring the patient into contact with the healing collective unconscious, largely through dream interpretation. Free association is also important, but the Jungian analyst, compared with the Freudian, plays a much more active role, and therapy is seen as a *cooperative venture* between patient and therapist (see Chapter 45).

CHAPTER SUMMARY

- Experimental/'general' psychology is concerned with psychological processes common to all human beings ('**universal norms**'). Personality differences represent one kind of '**group norm**' and reflect the **nomothetic approach**. The **idiographic approach** is concerned with discovering **individual/idiosyncratic norms**.
- Allport distinguished between **common** and **individual traits**. Individual traits can be **cardinal**, **central** and **secondary**. Most people possess a small number of central traits which compose the core of the personality.
- The nomothetic–idiographic distinction is based on a **false dichotomy**. They are increasingly being seen as complementary and interdependent approaches, and even Allport argued that both should be used together in order to achieve the aims of science.
- The **consistency controversy** was fuelled by Mischel, who rejected the **trait approach** in favour of **situationism**. **Interactionists** argue that all behaviour is the product of both personality and situational variables, and Mischel himself claims that it's the **psychological situation** that influences behaviour.
- **Orthogonal factor analysis** (FA) aims to identify a small number of powerful, **uncorrelated** factors (the method preferred by Eysenck), while **oblique** FA aims to identify a larger number of less powerful, **correlated** factors (preferred by Cattell).
- Eysenck uses the term 'type' for sets of correlated traits or **personality dimensions**, specifically **introversion–extroversion** (E), **neuroticism–stability** (N), which are both normally distributed, and **psychoticism** (P), which isn't.
- E, N and P are measured by the **Eysenck Personality Questionnaire** (EPQ). E and N are widely accepted as being reliable and valid, but there's much more doubt about P.
- Extroverts are chronically **under-aroused**, while introverts are chronically **over-aroused**. Compared with low N scorers, the sympathetic branch of the ANS reacts particularly strongly to stressful situations in high N scorers. The biological basis of P is much more uncertain, but male hormones may be involved.
- Introverts should be more easily **conditioned** than extroverts, but the evidence is equivocal. Eysenck assumes that conditionability is a unitary trait, but this has never been demonstrated and represents a weakness of the theory.
- Cattell has identified a number of **second-order**, surface traits, including **exvia–invia** and **anxiety**, corresponding to E and N respectively. Cattell claims that with psychiatric patients, Q-data reveal a **qualitative** difference between normals and psychotics.

- Compared with Eysenck, Cattell acknowledges the influence of situational factors on behaviour, as well as mood and state factors and motivational factors.
- There's a growing consensus that personality can be adequately described by five broad constructs/factors (the '**big five**'), namely **extroversion, agreeableness, conscientiousness, neuroticism/emotional stability** and **intelligence/openness to experience**.
- Kelly's **personal construct theory** (PCT) is both idiographic and phenomenological. The underlying model is **man the scientist. Personal constructs** are designed to make the world more predictable and controllable.
- PCT is more a total psychology than a personality theory. It's often called a **cognitive** theory of personality, and has been criticised for denying the subjective reality of emotional experience, as well as neglecting situational influences on behaviour.
- Like PCT, **humanistic theories** are rooted in **phenomenology** and **existentialism** and are concerned with uniquely human characteristics, including **self-actualisation**.
- The central concept in Rogers' theory is the **self**. Failure to maintain consistency between our self-image and our actions produces **incongruence**. Defence mechanisms may then be used, but these prevent the self from growing and changing, widening the gap between self-image and reality.
- To experience **positive self-regard**, our behaviour and experience must match our **conditions of worth**, but this can produce incongruence. The need for **positive regard** and positive self-regard are so strong that conditions of worth can supersede the values associated with self-actualisation.
- In **client-centred therapy**, the therapist provides **unconditional positive regard**, which enables the client to accept certain feelings and thoughts that are usually denied or distorted. In this way, **organismic values** gradually replace conditions of worth.
- Freud's **psychoanalytic theory** was the original **psychodynamic** theory, in which unconscious motivating forces play a central role. **Dreams, neurotic symptoms** and **defence mechanisms** represent three types of **compromise** through which the ego tries to meet the conflicting demands of the id and superego.
- **Dreams** consist of the **manifest content** and the **latent content** (the dream's meaning, namely, a **disguised wish fulfilment**). Dreams are created through **dream work**, with **symbols** playing a central role.
- **Neurotic symptoms** have a similar structure to dreams, which deflects the patient's attention away from the **pathogenic ideas** underlying the symptom.
- **Defence mechanisms** involve some degree of **self-deception** and **distortion of reality** which, in the short term, prevent us from being overwhelmed by anxiety. But as long-term solutions, they're unhealthy and undesirable.
- Our behaviour is **overdetermined** (one aspect of **psychic determinism**). The unconscious is revealed through **parapraxes**, including slips of the tongue ('Freudian slips').
- Freud's theories have generated a huge amount of empirical research. The most relevant studies are likely to be those which try to identify **mechanisms/processes** underlying unconscious phenomena.
- Psychoanalytic theory should be seen as a collection of hypotheses, some of which are more critical to the overall theory than others.
- Although Freud intended to produce a nomothetic theory, his work can be thought of as a set of **hermeneutic tools** that help to interpret underlying **meanings**. Although this kind of theory is difficult to test empirically, it has influenced our everyday understanding of ourselves.
- In Jung's **analytical psychology**, the Freudian unconscious is largely **personal**. It comprises much more than repressed material, including **complexes**.
- Complexes originate in the **collective/racial unconscious**, a reservoir of **primordial images** or **archetypes**, stemming from our ancestral past. Most important are the **persona, anima/animus**, the **shadow** and the **self**.
- Jungian **therapy** aims to bring the patient into contact with the healing collective unconscious, largely through dream interpretation.

Links with other topics/chapters

- Maslow's humanistic theory is probably best known for his *hierarchy of needs,* which is often discussed in relation to motivation (Chapter 5).
- The humanistic approach is one of the major *theoretical approaches* within psychology as a whole (Chapter 2).
- Eysenck's claim that differences between normals and neurotics/psychotics are quantitative (as opposed to qualitative) represents the *dimensional view of abnormality* (as opposed to the *categorical* view (Chapter 43).
- Eysenck (1995) points out that N and P represent only a *predisposition* ('diathesis'), unlike *neurosis* and *psychosis* which are actual *psychological disorders.* Under extreme stress, however, the predisposition can become a psychiatric illness (Claridge, 1985: Chapter 44).
- Lie scales (as used in the EPI) are used in *attitude scales* (Chapter 24).
- The effects of '*recreational*' *drugs* are usually discussed without taking individual differences such as personality into account (Chapter 8). In the case of

psychotropic drugs (used for treating psychological disorders), the focus is on the *disorder* (rather than the individual with the disorder) (Chapter 45).

- A way of testing the part of Eysenck's theory that deals with conditionability in the real world is through applying it to *criminality* (Chapter 46).
- Assessing personality through the use of forced-choice items on a questionnaire is an example of *reductionism* (Chapter 49).
- Traditionally, psychiatrists have distinguished between *neurotic disorders* (such as anxiety) and *psychotic disorders* (such as schizophrenia) (Chapter 43).
- A major criticism of *theories of social changes in ageing* is their neglect of individual differences. Instead of seeing all old people as the same, critics argue that we need to view how people age as continuous with their earlier personality (Chapter 39).
- Kelly's 'man the scientist' idea is consistent with Heider's common-sense psychology, which forms the basis of *attribution theory* (Chapter 23).
- *Dreams* and *dreaming* are an important feature of *rapid eye movement* (REM) *sleep* (Chapter 7).
- Both Freud and Skinner believed that *free will* is an illusion, although arguing from very different theoretical directions (Chapters 2 and 49).
- Jung's anima/animus archetype is related to Bem's concept of *psychological androgeny* (Chapter 36).

The concept of abnormality
- Abnormality as deviation from the average
- Abnormality as deviation from the norm
  - *Different kinds of norms*
- Abnormality as deviation from ideal mental health
- Abnormality as personal distress
- Abnormality as others' distress

PSYCHOLOGICAL ABNORMALITY: DEFINITIONS AND CLASSIFICATION

INTRODUCTION AND OVERVIEW

The emphasis in the preceding 42 chapters has been on normal psychological processes and development. However, we've also had occasion to qualify our discussion in two ways; first, by considering examples of abnormality (which also often serve to illuminate the normal); and second, by considering individual differences. This chapter brings these two issues together. Also, two whole chapters have been devoted to discussing abnormality in different ways: *substance abuse* (Chapter 8) and *exceptional development* (Chapter 40).

Clearly, normality and abnormality are two sides of a coin: each can be defined only in relation to the other. Also, implicit within this statement is the assumption that it's possible, and meaningful, to draw the line between normal and abnormal. Different criteria for defining normality/abnormality propose how and where the line can be drawn.

As we saw in Chapter 2, each of the major theoretical approaches discussed throughout this book – especially the *neurobiological/biogenic, psychodynamic, behavioural, humanistic,* and *cognitive* – defines psychological abnormality, and advocates ways of dealing with it, in its particular way. These will be discussed together in Chapter 45. By focusing here on the concept of abnormality itself, and how psychiatrists have attempted to classify mental disorders (*psychopathology:* see Chapter 44), we shall be discussing the *medical model.* This sees abnormality as *mental illness.*

THE CONCEPT OF ABNORMALITY

ASK YOURSELF...

- Try to think of some examples of people behaving in 'odd' or 'strange' ways.
- What does 'odd' or 'strange' really mean here?
- Would this behaviour be sufficient grounds for labelling the person – or their behaviour – as 'abnormal'?

Abnormality as deviation from the average

This represents the *literal* sense of abnormality, whereby any behaviour which isn't typical or usual (that is, infrequent) is, by definition, abnormal: 'normal' is 'average'. However, this *statistical criterion* doesn't help to distinguish between atypical behaviour which is desirable (or, at least, acceptable) and that which is undesirable and unacceptable. For example, creative genius (such as Picasso's) and megalomania (such as Hitler's) are both statistically rare (and according to this criterion abnormal), but the former would be rated as much more desirable than the latter.

Conversely, there are certain types of behaviour and experience which are so common as to be normal in the statistical sense, but which are regarded as constituting psychological disorders (such as anxiety and depression). So, the statistical criterion appears to be neither necessary nor sufficient as a way of defining abnormality.

Abnormality as deviation from the norm

The statistical criterion is insufficient because it's essentially *neutral;* that is, deviation from the average is neither good nor bad, desirable nor undesirable. *Deviation from the norm,* however, implies not behaving or feeling as one *should.* 'Norm' has an 'oughtness' about it: particular behaviours are expected from us at particular times and in particular situations, and if those expectations aren't met or are positively 'transgressed', we and/or our behaviour may be judged 'bad' or 'sick'.

For example, many people regard homosexuality as abnormal, not because it's statistically less common than heterosexuality, but because the 'normal' or 'natural' form of sexual behaviour in human beings is heterosexual. From a religious or moral perspective, homosexuality might be judged as 'bad', 'wicked' or 'sinful' (implying, perhaps, the element of choice). From a more biological or scientific perspective, it might be labelled 'sick', 'perverse' or 'deviant' (implying, perhaps, lack of choice).

Either way, even if it was found that a majority of men and women engaged in homosexual relationships (making *heterosexuality* abnormal according to the statistical criterion), these same people would still consider homosexuality a deviation from the norm and, therefore, abnormal. A further implication is that what's 'normal' is also 'desirable': unlike the statistical criterion, deviation from the norm doesn't allow for deviations which are also desirable.

Different kinds of norms

Within the same culture or society, a particular instance of behaviour may be considered normal or abnormal depending on the *situation* or *context.* For example, taking your clothes off is fine if you're about to step into a bath, but not if you're in the middle of a supermarket. However, *situational norms* aren't the only ones used to judge behaviour. *Developmental* (or *age*) *norms* dictate that, for instance, temper tantrums are perfectly normal in a two-year-old regardless of where they occur, but

Flagellants in the Philippines walk with bleeding wounds during an Easter re-enactment of Christ's crucifixion

decidedly abnormal in a 32-year-old (even in the privacy of his/her own home). *Cultural norms* are discussed below in relation to the ideal mental health criterion.

It's often far from obvious what norms are being broken when someone displays mental disorder: there's no law against being schizophrenic or having a panic attack, or being depressed, nor is it obvious what moral law or ethical principle is being broken in such cases. The kind of rule-breaking involved is discussed below in relation to the concept of mental illness.

Abnormality as deviation from ideal mental health

One way of 'fleshing out' the notion of desirability is to identify characteristics and abilities which people should possess for them to be considered normal. By implication, any lack or impoverishment of these characteristics and abilities constitutes abnormality or disorder.

Jahoda (1958) identified several ways in which mental health has been (or might be) defined, including:

- the absence of mental illness (clearly, a very negative definition)
- the ability to introspect, including the awareness of what we're doing and why
- the capacity for growth, development, and self-actualisation (as emphasised by Rogers and Maslow: see Chapters 9 and 42)
- integration of all the person's processes and attributes (e.g. balance between the id, ego and superego (Freud), and the achievement of ego identity (Erikson): see Chapters 37–39)
- the ability to cope with stress (see Chapter 12)
- autonomy (a concept that appears in many theories, including those of Erikson and Gould: see Chapter 38)
- seeing the world as it really is (part of Erikson's concept of ego identity)
- environmental mastery – the ability to love, work and play, to have satisfying interpersonal relationships, and to have the capacity for adaptation and adjustment (Erikson's ego identity again, and Freud's *lieben* und *arbeiten* – love and work).

ASK YOURSELF...

- Is it possible to construct a list of ideals that everyone would agree with?
- What's wrong with this approach to defining normality?

While many or all these criteria of mental health may seem valid and are intuitively appealing, their claim to be universal and absolute raises serious problems.

- According to these criteria, most of us would be considered maladjusted or disordered. For example, according to Maslow most of us don't achieve self-actualisation, so there's a fundamental discrepancy between these criteria and the statistical criterion (Mackay, 1975).
- Although many psychologists would accept these criteria, they're essentially *value judgements,* reflecting what's considered to be an ideal state of being human. By contrast, there's little dispute as to the precise nature of physical health. According to Szasz (1962), 'The norm is the structural and functional integrity of the human body', and if there are no abnormalities present, the person is considered to be in good health. Judgements about physical health don't involve making moral or philosophical decisions. 'What health is can be stated in anatomical and physical terms' (Szasz, 1962): ideal and statistical criteria tend to be roughly equivalent (Mackay, 1975).
- It follows that what's considered to be psychologically normal (and, hence, abnormal) depends upon the culture in which a person lives. Psychological normality and abnormality are *culturally defined* (unlike physical normality and abnormality which, Szasz believes, can be defined in universally applicable ways).

Oscar Wilde (1854–1900), the Irish writer, was imprisoned for homosexuality in 1895

CRITICAL DISCUSSION 43.1 Homosexuality – shifting definitions of abnormality

- DSM-II (the second edition of the American Psychiatric Association's [APA] official classification of mental disorders, published in 1968) included homosexuality as a sexual deviation.
- In 1973, the APA Nomenclature Committee, under pressure from many professionals and gay activist groups, recommended that the category should be removed and replaced with 'sexual orientation disturbance'. This was

to be applied to gay men and women who are 'disturbed by, in conflict with, or wish to change their sexual orientation'. The change was approved, but not without fierce protests from several eminent psychiatrists who maintained the 'orthodox' view that homosexuality is inherently abnormal.

- When DSM-III was published in 1980, another new term, *ego-dystonic homosexuality* (EDH) was used to refer to someone who is homosexually aroused, finds this arousal to be a persistent source of distress, and wishes to become heterosexual.
- Since homosexuality itself was no longer a mental disorder, there was no inclusion in DSM-III of predisposing factors (as there was for all disorders). But they *were* included for EDH, namely, the individual homosexual's internalisation of society's negative attitudes (*homophobia* – fear of homosexuals – and *heterosexism* – anti-homosexual prejudice and discrimination). So, according to DSM-III, a homosexual is abnormal if s/he has been persuaded by society's prejudices that homosexuality is inherently abnormal, but at the same time it denied that homosexuality in itself is abnormal (Davison *et al.*, 2004).
- Not surprisingly, no such category as 'ego-dystonic heterosexuality' has ever been used (Kitzinger, 1990). When DSM-III was revised (DSM-III-R, 1987), the APA decided to drop EDH (which was rarely used). However, one of the many 'dustbin' categories, 'sexual disorder not otherwise specified', includes 'persistent and marked distress about one's sexual orientation'; this has been retained in DSM-IV (1994) and DSM-IV-TR (2000).
- ICD-10 (1992), the latest edition of the World Health Organization's classification of diseases, also includes 'ego-dystonic sexual orientation' under 'disorders of adult personality and behaviour'.
- In the UK up until the 1960s, homosexuality among consenting adults was illegal; in 1995 the age of consent was lowered to 18. Clearly, nothing has happened to homosexuality itself during the last 30 years or so. What has changed are attitudes towards it, which then became reflected in its official psychiatric and legal status. Homosexuality *in itself* is neither normal nor abnormal, desirable nor undesirable, and this argument can be extended to behaviour in general.

Abnormality as personal distress

From the perspective of the individual, abnormality is the subjective experience of intense anxiety, unhappiness, depression, or a whole host of other forms that personal distress/suffering can take. While this may often be the only indication that anything is wrong (and may not necessarily be obvious to others), it may be a sufficient reason for seeking professional help. As Miller & Morley (1986) say:

> People do not come to clinics because they feel they have met some abstract definition of abnormality. For the most part they come because their feelings or behaviour cause them distress ...

However, the converse is also sometimes true: someone whose behaviour is obviously 'mad' as far as others are concerned may be oblivious of how others see them and may experience *no* subjective distress. This is sometimes referred to as *lack of insight* and is a feature of *psychosis* (see Table 43.4, page 767).

Abnormality as others' distress

If the person seen by others as behaving abnormally is the last to recognise there's a problem, then others' concern may act as a counterbalance to his/her lack of insight. This suggests, as with all behaviour, that abnormality is *interpersonal* and not simply *intrapersonal/intrapsychic*. In other words, it takes place *between* people, in social situations, and isn't merely a reflection of an individual actor's personal qualities or characteristics (see Chapter 42).

From a practical and ethical perspective, this is a double-edged sword: others' distress may be both a 'blessing' (literally a life-saver, as in the case of someone who's unaware of the self-destructive nature of his/her drug abuse) and a curse (such as when a parent is distressed about a son or daughter's homosexuality, with which the person may feel perfectly comfortable). The former could be called *empathic concern*, where the 'helper' has an altruistic desire to reduce the other's distress, while in the latter, the helper's *personal distress* produces an egoistic desire to reduce his/her own distress. The question is, whose distress is the helper trying to reduce?

Abnormality as maladaptiveness

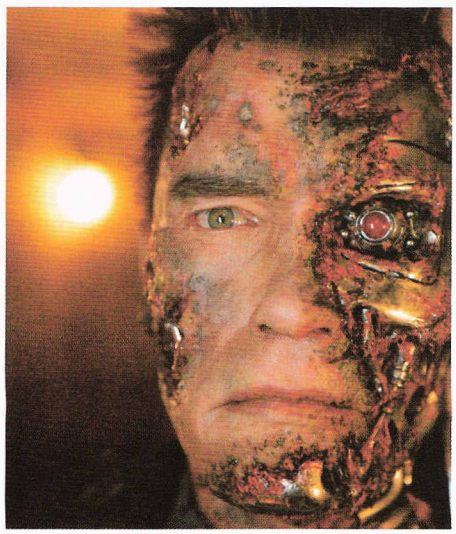
Behaviour may be seen as abnormal if it prevents people from pursuing and achieving their goals, or doesn't contribute to their personal sense of well-being, or prevents them from functioning as they would wish in their personal, sexual, social, intellectual and occupational lives. For example, drug abuse (or substance-related disorder) is defined mainly by how it produces social and occupational disability, such as poor work performance and serious marital arguments. Similarly, a fear of flying might prevent someone from taking a job promotion (Davison & Neale, 1994).

Although the emphasis here is on the *consequences* of the behaviour, such behaviours may be very distressing in themselves for the person concerned. For example, phobias are negative experiences, because they involve intense fear, regardless of any practical effects brought about by the fear.

Abnormality as unexpected behaviour

According to Davison *et al.* (2004), it's abnormal to react to a situation or event in ways that couldn't be (reason-

ably) predicted, given what we know about human behaviour. For example, *anxiety disorders* are diagnosed when the anxiety is 'out of proportion to the situation'. The problem with this criterion is: who decides what's 'in proportion'? Is it just another form of deviation from the average, whereby what's reasonable or acceptable is simply how most people would be expected to behave? By this definition, *under-reacting* is just as abnormal as over-reacting, and yet only the latter is usually seen as a problem.



Abnormality as highly predictable/unpredictable behaviour

ASK YOURSELF...

- In light of the discussion of the *consistency controversy* in Chapter 42 (see pages 734–736), how might abnormality be defined in terms of the consistency of behaviour?

If we have generalised expectations about people's typical reactions to particular kinds of situation, then a person's behaviour is predictable to the extent that we know about the situation. However, not all situations are equally powerful influences on behaviour, and so cannot be used equally to predict a person's behaviour. It follows that it's normal for any individual's behaviour to be only *partially* predictable or consistent and, in turn, that it's abnormal for a person to display either *extremely predictable* or *extremely unpredictable* behaviour.

If people act so consistently that they seem to be unaffected by situations (including the other people involved), it's almost as if they're machines (or *automata*). For example, someone suffering from *paranoid delusions* may see the world entirely in terms of others' harmful intentions.

Arnold Schwarzenegger in *Terminator*

This may, in turn, elicit certain kinds of responses in others, which may reinforce the delusions. According to Smith *et al.* (1986), people with behaviour disorders are unable to modify their behaviour in response to changing environmental requirements; their behaviour is maladaptive because it's inflexible and unrealistic. Equally, someone whose behaviour is very unpredictable is very difficult to interact with. People with *schizophrenia* are often perceived as embodying this kind of unpredictability, which is unnerving and unsettling – for others!

Abnormality as mental illness

Many writers (e.g. Maher, 1966) have pointed out that the vocabulary we use to refer to psychological disorder is borrowed from medical terminology: deviant behaviour is referred to as *psychopathology,* is classified on the basis of *symptoms,* the classification being called a *diagnosis,* the methods used to try to change the behaviour are called *therapies,* and these are often carried out in *mental* or *psychiatric hospitals.* If the deviant behaviour ceases, the patient is described as *cured.*

Other related terms are *syndrome, prognosis,* and *in remission.* This way of talking about psychological abnormality reflects the pervasiveness of a 'sickness' (or medical) model. Whether we realise it or not, when we think about abnormal behaviour we tend to think about it as if it were indicative of some underlying illness.

How valid is the medical model?

ASK YOURSELF...

- Try to formulate arguments for and against seeing abnormal behaviour as indicating mental illness.

Many defenders of the medical model have argued that it's more humane to regard a psychologically disturbed person as sick (or mad) than plain bad (it's more stigmatising to be regarded as morally defective: Blaney, 1975). However, when we label people as sick or ill, we're removing from them all responsibility for their behaviour. Just as we don't normally hold someone responsible for having cancer or a broken leg, so 'mental illness' implies that something has *happened to* the person. S/he is a victim who is, accordingly, put in the care (and often the custody) of doctors and nurses who'll take over responsibility.

The stigma attached to mental illness may actually be *greater* than that attached to labels of 'bad', because our fear of mental illness is even greater than our fear of becoming involved in crime or other immoral activities. This, in turn, is based on our belief that while illness 'just happens to people' (we've no control over it), at least there's some degree of *choice* involved in criminal activity.

CRITICAL DISCUSSION 43.2 Is psychiatry value-free?

- As we saw in relation to homosexuality (see Critical Discussion 43.1), norms change within the same culture over time. Hence, the criteria used by psychiatry to judge abnormality must be seen in a *moral context*, not a medical one (Heather, 1976). Psychiatry's claim to be an orthodox part of medical science rests upon the concept of mental illness, but far from being another medical speciality, psychiatry is a 'quasi-medical illusion' (Heather, 1976).
- Similarly, Szasz (1962) argues that the norms from which the mentally ill are thought to deviate have to be stated in psychological, ethical, and legal terms, and yet the remedy is sought in terms of medical measures. For this reason, Szasz believes that the concept of mental illness has replaced beliefs in demonology and witchcraft:

  Mental illness thus exists or is 'real' in exactly the same sense in which witches existed or were real ...

- It also serves the same *political* purposes. Whenever people wish to exclude others from their midst, they attach to them stigmatising labels (e.g. 'foreigner', 'criminal', 'mentally ill') (Littlewood & Lipsedge, 1997). Unlike people suffering from physical illness, most people considered to be mentally ill (especially those 'certified' or 'sectioned' and so legally mentally ill) are so defined by *others* (relatives, friends, employers, police, and so on). They've upset the social order (by violating or ignoring social laws and conventions), and so society labels them as mentally ill and (in many cases) 'punishes' them by committing them to a mental hospital (Szasz, 1974).

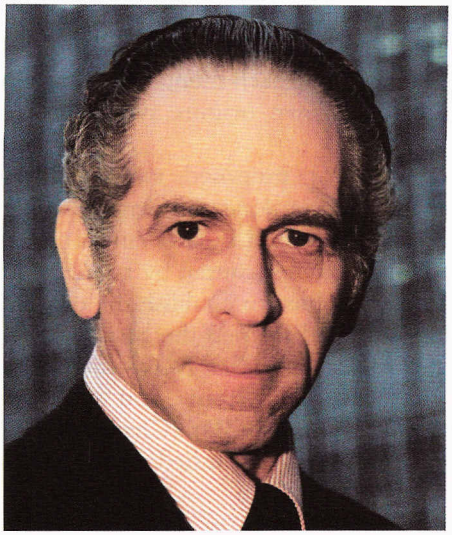
During the Middle Ages, what we'd now call mental disorder was seen as possession by the Devil or as witchcraft

Diagnostic labelling as a form of control

As we noted earlier, people considered to be 'mentally ill' are often unpredictable, something others find disturbing. Indeed, it's usually others who are disturbed by the patient's behaviour, rarely the patient (Laing, 1967). Attaching a diagnostic label represents a 'symbolic recapture' and this may be followed by a physical capture (hospitalisation, drugs, and so on: Szasz, 1974).

While medical diagnosis usually focuses only on the damaged or diseased parts of the body, psychiatric diagnosis describes the *whole person* – someone doesn't 'have' schizophrenia but *is* schizophrenic. This represents a new and total identity, which describes not only the person but also how s/he should be regarded and treated by others. Psychiatric diagnosis, therefore, is a form of *action*. (We should note that DSM-IV-TR explicitly *rejects* the use of labels such as 'schizophrenic', and recommends instead 'an individual with schizophrenia'.)

What are schizophrenics doing wrong?



In what ways are schizophrenics unpredictable, and what kinds of rules are they breaking? According to Scheff (1966), they're breaking *residual rules,* the 'unnameable' expectations we have regarding such things as 'decency' and 'reality'. These rules are themselves implicit, taken for granted and not articulated, which makes behaviour that violates them difficult to understand and also difficult to articulate. This is what makes it seem strange and frightening.

According to Becker (1963), psychiatric intervention is based, generally speaking, on middle-class values regarding decent, reasonable, proper behaviour and experience. These are then applied to working-class patients, who constitute the vast majority of the inmates of psychiatric hospitals.

Mental illness or problems in living?

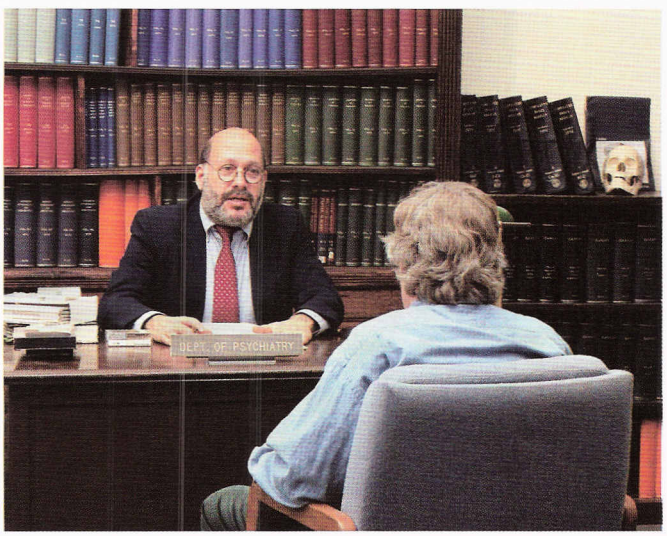
Szasz (e.g. 1962) is probably the most radical critic of the concept of mental illness. He argues that the basic assumption made by psychiatrists is that 'mental illness' is caused by diseases or disorders of the nervous system (in particular, the brain), which are revealed in abnormal thinking and behaviour. If this is the case, it would be better to call them 'diseases of the brain' or *neurophysiological disorders.* This would then get rid of any confusion between physical, organic defects (which must be seen in an anatomical and physiological context) and 'problems in living' the person may have (which must be seen in an ethical and social context).

Szasz argues that the vast majority of cases of 'mental illness' are actually cases of problems of living. It's the exception rather than the rule to find a 'mentally ill' person who's actually suffering from some organic brain disease (such as in Alzheimer's disease, or alcohol poisoning). This has traditionally been recognised by psychiatrists themselves, who distinguish between *organic*

Thomas Szasz (born 1920)

and *functional psychosis*. 'Functional' means that there's no demonstrable physical basis for the abnormal behaviour and that something has gone wrong with how the person functions in the network of relationships which make up their world (Bailey, 1979).

However, many psychiatrists believe that medical science will, in time, identify the physical causes of functional disorders (which include schizophrenia and psychotic depression). Indeed, many claim that this point has already been reached (see Chapter 44). Yet according to Heather (1976), such evidence wouldn't cover all major categories of mental disorder (in particular, neurosis and personality disorder). Not even the most organically oriented psychiatrists would claim that these are bodily diseases in any sense!



Box 43.1 Does the concept of mental illness make sense?

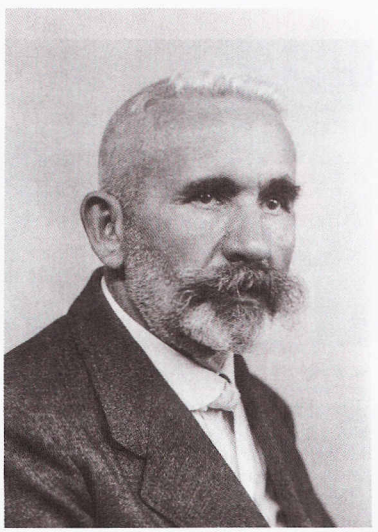
- If, in most cases, it's not the brain that's diseased, in what sense can we think of the mind as being diseased? For Szasz, it's only in a *metaphorical* sense that we can attribute disease to the mind. In a literal sense, it's logically impossible for a non-spatial, non-physical mind to be suffering from a disorder of a physicochemical nature.
- Szasz doesn't deny that the problem behaviours that mental health professionals see as indicative of mental illness are often strange, irritating, and deviant. They may also be distressing for the person concerned. But they're *not* a symptom of underlying brain disease.
- According to Bailey (1979), medicine began by classifying such things as syphilis and tuberculosis as illnesses, all sharing the common feature of a state of disordered structure and/or functioning of the human body as a physicochemical machine. The mistake was to keep adding items to this list which aren't illnesses in this sense. Agreeing with Szasz, Bailey maintains that:
  - organic mental illnesses *aren't* mental illnesses at all but physical illnesses, in which mental symptoms are manifested and which aid diagnosis and treatment
  - functional mental illnesses aren't illnesses but *disorders of psychosocial or interpersonal functioning* (Szasz's 'problems in living'), in which mental symptoms are important in deciding the type of therapy the patient requires.

Diagnosis in general medicine and psychiatry

An important difference between diagnosis in general medicine and psychiatry is in the role of *signs* and *symptoms*. When doctors diagnose physical illnesses, they look for signs of disease (the results of objective tests, such as blood tests and X-rays, as well as physical examination) and symptoms (the patient's report of pain, and so on). They tend to attach more weight to the former. By contrast, psychiatrists are much more at the mercy of symptoms. Although psychological tests are the psychiatric equivalent of blood tests and X-rays, they're nothing like as reliable and valid (see Chapters 41 and 42) and, in practice, the psychiatrist will rely to a large extent on the patient's own description of the problem.

However, observation of the patient's behaviour, talking to relatives and others about the patient's behaviour and, increasingly, the use of brain-scanning techniques (such as CAT and PET: see below and Chapter 4) also contribute data regarding the signs of the illness. This is especially true in the case of serious disorders, such as schizophrenia. Nevertheless, the two major classification systems used by psychiatrists today, DSM and ICD, are based largely on the abnormal experiences and beliefs reported by patients, because we have no objective or biological markers for most neurotic or psychotic disorders (Frith & Cahill, 1995).

A patient being assessed by a psychiatrist



During the late 1970s, the APA considered including a formal statement in DSM-III (1980) to the effect that mental disorders are a subset of medical diseases (Lilienfeld, 1995). While this proposal was eventually rejected, it sparked a storm of protests from psychologists, as well as many psychiatrists. The implication of the proposal was that the distinction between organic and functional disorders is invalid, and that all disorders are organic.

A major change that took place in DSM-IV (1994) compared with DSM-III-R (1987) was the removal of the category of 'organic mental disorders' and its replacement with 'delirium, dementia, amnesic and other cognitive disorders' (see Table 43.1). According to Davison & Neale (1994), the thinking behind this change is that the term 'organic' implies that the other major categories don't have a biological basis. Since research has shown the influence of biological factors through a whole range of disorders, it's now considered misleading to use the term 'organic'. To this extent, the concept of psychological abnormality is even more *medicalised* than it's ever been. However, ICD retains a separate category for organic disorders.

THE CLASSIFICATION OF MENTAL DISORDERS

A brief history

An integral part of the medical model is the classification of mental disorder and the related process of diagnosis. All systems of classification stem from the work of Kraepelin, who published the first recognised textbook of psychiatry in 1883. Kraepelin claimed that certain groups of symptoms occur together sufficiently often for them to be called a 'disease' or syndrome. In other words, there's an underlying physical cause, just as a physical disease may be attributed to a physiological dysfunction (Davison *et al.*, 2004). He regarded each mental illness as distinct from all others, with its own origins, symptoms, course, and outcome.

Emil Kraepelin (1856–1926)

Kraepelin (1896) proposed two major groups of serious mental diseases: *dementia praecox* (the original term for schizophrenia), caused by a chemical imbalance, and *manic–depressive psychosis* (caused by a faulty metabolism). His classification helped to establish the organic nature of mental disorders, and formed the basis for the *Diagnostic and Statistical Manual of Mental Disorders* (DSM), the APA's official classification system, and the *International Classification of Diseases* (ICD) (Chapter 5: 'Mental and behavioural disorders') published by the World Health Organization.

DSM-I was published in 1952, DSM-II in 1968, followed by DSM-III (1980), DSM-III-R (1987), DSM-IV (1994), and DSM-IV-TR (2000: TR stands for 'Text Revision'). Mental disorders were included in ICD for the first time in 1948 (ICD-6) and ICD-10 was published in 1992. Table 43.1 shows the major categories of both ICD-10 and DSM-IV-TR. Table 43.2 shows ten major categories, with examples of specific disorders based on both classification schemes.

Kraepelin's classification is also embodied in the Mental Health Act 1983 (in England and Wales). The Act identifies three major categories of mental disturbance/disorder, namely, *mental illness* (neurosis and psychosis, the latter subdivided into organic and functional), *personality disorder* (including psychopathy), and *mental impairment*.

Comparing DSM-IV-TR and ICD-10

Broad similarities and differences

Table 43.1 shows how the two systems overlap. One of the major differences between them is the number of major categories. Most differences arise because DSM-IV-TR uses a larger number of discrete categories to classify disorders that appear under a smaller number of more general categories in ICD-10. However, this is also reversed in one instance, as shown in Figure 43.2 (see page 766).

Neither system actually uses the term 'mental illness'. Instead, they use the term *mental disorder,* which is defined by DSM-IV-TR as:

> A clinically significant behaviour or psychological syndrome or pattern that occurs in a person and that is associated with present distress (a painful symptom) or disability (impairment of one or more important areas of functioning) or with a significantly increased risk of suffering death, pain, disability, or an important loss of freedom. In addition, this syndrome or pattern must not be merely an expectable response to a particular event, for example, the death of a loved one ... (APA, 2000)

Table 43.1 The major categories of mental disorder as identified by DSM-IV-TR and ICD-10

DSM-IV-TR	ICD-10
1 Delirium, dementia, amnesic and other cognitive disorders	**1** Organic, including symptomatic, mental disorders
2 Schizophrenic and other psychotic disorders	**2** Schizophrenia, schizotypal and delusional disorders
3 Substance-related disorders	**3** Mental and behavioural disorders due to psychoactive substance use
4 Mood disorders	**4** Mood (affective) disorders
5 Anxiety disorders	**5** Neurotic, stress-related and somatoform disorders
6 Somatoform disorders	
7 Dissociative disorders	
8 Adjustment disorders	
9 Disorders usually first diagnosed in infancy, childhood or adolescence including mental retardation – (Axis II)*	**6** Behavioural and emotional disorders with onset usually occurring in childhood and adolescence
	7 Disorders of psychological development
	8 Mental retardation
10 Personality disorders (Axis II)*	**9** Disorders of adult personality and behaviour
11 Sexual and gender identity disorders	
12 Impulse control disorders not elsewhere classified	
13 Factitious disorders	
14 Sleep disorders	**10** Behavioural syndromes associated with physiological disturbances and physical factors
15 Eating disorders	
16 Other conditions that may be a focus of clinical attention	**11** Unspecified mental disorder

* see Table 43.3

'Mental disorder' is used by ICD-10:

> ... to imply the existence of a clinically recognisable set of symptoms or behaviour associated in most cases with distress and with interference with personal functions ... (WHO, 1992)

Although we noted earlier that DSM has become more organic in its approach, Cooper (1994) argues that only a few psychiatric diagnoses are associated with disturbed anatomy or physiology. Use of the term 'disorder' avoids the need to debate the meaning or value of 'disease' or 'illness'.

Table 43.2 Major categories of mental disorder, with examples, based on DSM-IV-TR and ICD-10

Organic mental disorders: Delirium. Dementia due to: Alzheimer's disease; Creutzfeldt–Jakob disease (human version of BSE: 'mad cow disease'); HIV; Huntington's chorea; Parkinson's disease. Brain infections. Brain tumours. Brain damage
Schizophrenia and related psychotic disorders: Schizophrenia: paranoid; hebephrenic (disorganised); catatonic; simple; undifferentiated. Schizotypal disorder. Delusional disorder (paranoia). Schizophreniform disorder. Schizoaffective disorder. Brief reactive psychosis
Psychoactive substance use disorders: Intoxication, harmful use/abuse, dependence, withdrawal state re: alcohol; amphetamines; caffeine (and other stimulants); cannabis (cannabinoids); cocaine; hallucinogens; inhalants/volatile solvents; tobacco (nicotine); opioids; sedatives/hypnotics/anxiolytics; phencyclidine
Mood (affective) disorders: Depressive disorder (unipolar); manic disorder (bipolar 1); bipolar 2 disorders; mood disorder with seasonal pattern (seasonal affective disorder/SAD); mood disorder with postpartum onset (postnatal depression); premenstrual dysphoric disorder (premenstrual disorder/PMD); dysthymic disorder; cyclothymic disorder
Neurotic disorders: Anxiety disorders. Phobic anxiety disorders. Obsessive-compulsive disorders. Panic disorder. Dissociative disorders: dissociative amnesia (psychogenic amnesia); dissociative fugue (psychogenic fugue); dissociative identity disorder (multiple personality disorder); depersonalisation. Somatoform disorders. Hypochondriasis. Post-traumatic stress disorder
Disorders of infancy, childhood and adolescence: Autistic disorder. Attention-deficit/disruptive behaviour disorders: hyperkinetic disorder; conduct disorder. Separation anxiety disorder. Elective mutism. Tic disorders (e.g. Tourette's disorder). Enuresis. Encopresis. Stuttering. Disorders of speech and language. Specific developmental disorders of scholastic skills. Learning disorders
Mental retardation: Mild/Moderate/Severe/Profound. Associated with: genetic (e.g. chromosome) abnormalities; gross disease of the brain; antenatal damage; perinatal damage; postnatal damage; malnutrition
Personality disorders (disorders of adult personality): Antisocial (psychopathic). Paranoid. Schizoid (schizotypal). Anxious/avoidant. Dependent. Obsessive–compulsive. Emotionally unstable. Histrionic. Narcissistic. Pathological gambling. Pyromania. Kleptomania. Trichotillomania. Factitious disorder
Eating and sleeping disorders: Anorexia nervosa. Bulimia nervosa. Insomnia. Hypersomnia. Sleepwalking (somnambulism). Sleep (night) terrors
Sexual and gender identity disorders: Sexual desire disorders. Sexual arousal disorders. Paraphilias: exhibitionism; fetishism; voyeurism; paedophilia; frotteurism; transvestism; sexual sadism; sexual masochism. Transsexualism

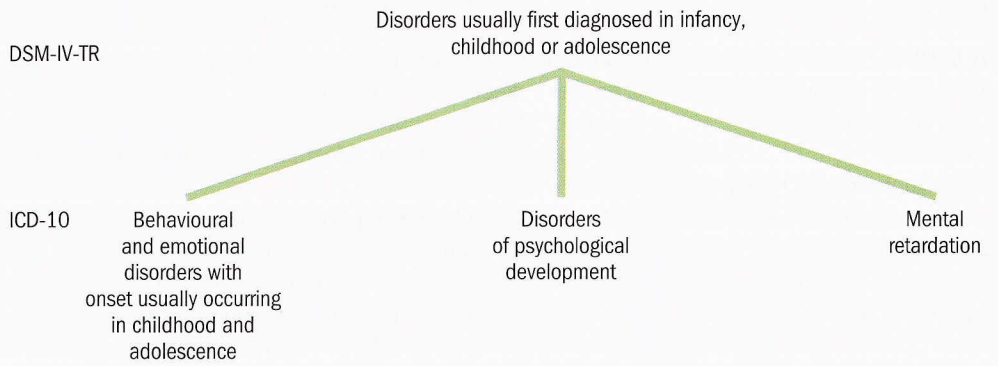


Figure 43.2 An example of how a general DSM-IV-TR category incorporates three ICD-10 categories

Multi-axial classification

DSM-IV-TR

One of the major changes made in DSM-III (1980) compared with DSM-II (1968), was the introduction of a *multi-axial system* of classification. Whereas DSM-II required only a simple diagnostic label (e.g. 'schizophrenia' or 'anxiety neurosis'), DSM-III (and subsequent editions) instructed the psychiatrist to evaluate the patient on five different axes, which represent different areas of functioning (see Table 43.3).

The inclusion of the axes reflects the assumption that most disorders are caused by the *interaction* of biological, psychological, and sociological factors. Instead of simply placing someone in a single clinical category (e.g. schizophrenia), the patient is assessed much more broadly, giving a more global and in-depth picture. While axes 1–3 are compulsory, 4 and 5 are optional. An important change made in DSM-IV compared with DSM-III-R was the 'return' of most developmental disorders to Axis I, with the exception of mental retardation.

ICD-10

According to Cooper (1994), it's often assumed that ICD-10 has only a single axis. However, although it doesn't have separate axes in the way that DSM has, built into the groupings of the disorders are broad types of *aetiology* (causal factors), such as organic causes, substance use and stress.

When ICD-10 was being constructed, it was agreed that, because of the incomplete and often controversial state of knowledge about the aetiology of most psychiatric disorders, the classification would be worked out on a *descriptive* basis. This implies, strictly, that disorders should be grouped according to similarities and differences of symptoms and signs, so that a particular disorder should occur in only one place. But it soon became clear that this wouldn't appeal to clinicians, who like to be able to give prominence to aetiology wherever possible (hence the inclusion of the broad types of aetiology within the categories). Although this makes ICD-10 impure from a *taxonomic* (classificatory) point of view, it's

Table 43.3 The five axes of DSM-IV-TR

Axis I: Clinical syndromes (diagnostic category) **and other conditions that may be a focus of clinical attention**	This lists all mental disorders and the criteria for rating them, except personality disorders and mental retardation. 'Other conditions' may include problems related to abuse or neglect, academic problems, and 'phase of life' problems
Axis II: Personality disorders; mental retardation	These life-long, deeply ingrained, inflexible and maladaptive traits and behaviours may occur quite independently of Axis I clinical syndromes
Axis III: General medical conditions	Any medical condition that could affect the patient's mental state. For example, how might heart disease/diabetes/cancer affect mood and cognitive abilities, as well as response to treatment?
Axis IV: Psychosocial and environmental problems	Stressful events that have occurred within the previous year (e.g. divorce, death of parent or spouse), which could be contributory factors and/or which might influence the course of treatment. Rated on a scale of 1–7 (7 indicates 'catastrophic')
Axis V: Global assessment of functioning	How well has the patient performed during the previous year, in social relationships, leisure activities and at work? On the global assessment of functioning scale, 0 denotes 'persistent danger', 100 denotes 'superior functioning'

much more likely to be used by clinicians (Cooper, 1994). In DSM-IV-TR, assumptions about causation *aren't* used in making a diagnosis (it's *atheoretical*).

Neurosis and psychosis

Both systems have dropped the traditional distinction between neurosis and psychosis, although ICD-10 retains the term 'neurotic' and DSM-IV-TR retains the term 'psychotic'. According to Gelder *et al.* (1989, 1999), there are four major reasons for getting rid of the distinction:

- there are exceptions to all the criteria used to distinguish them (see Table 43.4 below)
- disorders included under the broad categories of 'neurosis' or 'psychosis' have little in common
- it's less informative to classify a disorder as neurotic or psychotic than to classify it as a particular disorder within that very broad category (e.g. 'schizophrenic' is more informative than 'psychotic')
- DSM-III wanted to remove the psychoanalytic influence in the way 'neurotic' was used and understood (based on Freud's theories); but in everyday psychiatric practice they're convenient terms for disorders which cannot be given more precise diagnoses, and also the terms are still in general use (as in 'antipsychotic drugs' and when referring to symptoms).

Table 43.4 The major criteria for making the traditional distinction between neurosis and psychosis

Neurosis	Psychosis
Only part of the personality is involved/affected	The whole personality is involved/affected
Contact with reality is maintained	Contact with reality is lost, e.g. hallucinations and delusions represent the inability to distinguish between subjective experience and external reality
Neurotics have *insight* (that is, recognise they have a problem)	Psychotics lack insight
Neurotic symptoms/behaviour can be seen as an exaggeration of 'normal' behaviour (the difference is *quantitative*)	Psychotic symptoms/behaviour are discontinuous with 'normal' behaviour (the difference is *qualitative*)
Often begins as response to a stressor	There's usually no precipitating cause
The neurotic disturbance is related to the patient's previous personality (the premorbid personality)	The psychotic disturbance *isn't* related to the patient's premorbid personality
Treated mainly by *psychological* methods	Treated mainly by *physical* (somatic) methods

Table 43.4 implies that psychosis is a very much more serious form of mental disorder than neurosis. According to Frith & Cahill (1995), psychosis is the technical term for what the lay person calls madness. In contrast to the symptoms of neurosis, psychotic symptoms (in particular delusions, hallucinations, passivity experiences, and thought disorder) are outside the normal realm of experience and, as such, are outside our common-sense powers of understanding and empathy. It's these aspects of psychotic symptoms that isolate the person in 'a world of their own'.

Bethlam Royal Hospital, London ('Bedlam'), the world's oldest institution for those with mental disorders

Schizophrenia is by far the commonest of the psychoses: the lifetime risk of having a schizophrenic breakdown is 0.5–2 per cent, compared with 0.6–1.1 per cent for affective psychosis, and, despite powerful drugs, about two-thirds of schizophrenics suffer recurring episodes. Delusions are by far the commonest of the psychotic symptoms. According to Jasper (1962, in Frith & Cahill, 1995):

> Since time immemorial, delusion has been taken as the basic characteristic of madness. To be mad was to be deluded.

The use of diagnostic criteria

Both DSM and ICD have introduced explicit operational criteria for diagnosis (based on Spitzer *et al.*'s, 1978, *Research Diagnostic Criteria*). For each disorder, there's a specified list of symptoms, all or some of which must be present, for a specified period of time, in relation to age and gender, stipulation as to what other diagnoses mustn't be present, and the personal and social consequences of the disorder. The aim is to make diagnosis more reliable and valid (see below) by laying down rules for the inclusion or exclusion of cases.

Cultural influences on mental disorder

Cooper (1994) asks whether the *social consequences* should be included among the defining features of a disorder itself, especially within an internationally used system such as ICD, since the social environment of individuals varies so widely between cultures:

> The same symptoms and behaviour that are tolerated in one culture may cause severe social problems in another culture, and it is clearly undesirable for diagnostic decisions to be determined by cultural and social definitions.

Cooper seems to be saying that definitions of normality/abnormality are *culturally relative* (see the earlier discussion of abnormality as deviation from the norm). But he also implies that it's possible to diagnose mental disorders independently of cultural norms, values, and worldviews. This raises the fundamental question as to whether mental disorders exist in some objective sense. Just as modern medicine is based on the assumption that physical illness is the same throughout the world, and that definition, classification, causation, and diagnosis are largely unaffected by cultural factors, so biologically orientated psychiatrists argue that organic psychoses, in particular schizophrenia and depression, are also 'culture-free'.

CRITICAL DISCUSSION 43.3 Is schizophrenia culture-free?

During the 1970s and 1980s, psychiatrists and clinical psychologists became increasingly interested in 'cultural psychiatry'. According to Berry *et al.* (1992), the central issue in the cross-cultural study of mental disorder is whether phenomena such as schizophrenia are:

- *absolute* – found in all cultures in precisely the same form
- *universal* – present in some form in all cultures, but subject to cultural influence
- *culturally relative* – unique to particular cultures and understandable only in terms of those cultures.

Of these three possibilities, only the first corresponds to a 'culture-free' view of abnormality. Berry *et al.* reject this view of abnormality, on the grounds that:

> ... cultural factors appear to affect at least some aspects of mental disorders, even those that are so closely linked to human biology.

Universality is a more likely candidate for capturing the objective (biological) nature of mental disorder. Schizophrenia is the most commonly diagnosed mental disorder in the world, and of the major disorders, the largest number of culture-general symptoms has been reported for schizophrenia (WHO, 1973, 1979; Draguns, 1980, 1990).

However, according to Brislin (1993), there are at least three possible ways in which culture-specific factors can influence schizophrenia: (i) the form that symptoms will take, (ii) the precipitatory factor involved in the onset of the illness, and (iii) the prognosis.

(i) When schizophrenics complain that their minds are being invaded by unseen forces, in North America and Europe these forces keep up to date with technological developments. So, in the 1920s, these were often voices from the radio; in the 1950s, they often came from TV, in the 1960s it was satellites in space, and in the 1970s and 1980s spirits were transmitted through microwave ovens. In cultures where witchcraft is considered common, the voices or spirits would be directed by unseen forces under the control of demons.

(ii) Day *et al.* (1987) studied schizophrenia in nine different locations in the USA, Asia, Europe, and South America. Acute schizophrenic attacks were associated with stressful events 'external' to the patients (such as losing one's job, unexpected death of spouse), which tended to cluster within a two- to three-week period before the onset of obvious symptoms. Some events could only be understood as stressful if the researchers had considerable information about the cultural background of the sample.

(iii) Lin & Kleinman (1988) found that the prognosis for successful treatment of schizophrenia was better in non-industrialised than industrialised societies. The former provide more structured, stable, predictable, and socially supportive environments that allow schizophrenic patients to recover at their own pace and to be reintegrated into society.

A large number of studies have found that, in a wide range of non-western cultures, there are apparently unique ways of 'being mad' (Berry *et al.*, 1992) – that is, there are forms of abnormality that aren't easily accommodated by the categories of ICD or DSM. These *culture-bound syndromes* (CBSs) or 'exotic' disorders are first described in, and then closely or exclusively associated with, a particular population or cultural area, with the local, indigenous name being used. DSM-IV-TR defines them as:

> ... locality-specific patterns of aberrant behaviour and troubling experience that may or may not be linked to a persistent DSM-IV diagnostic category ... (APA, 2000)

For example, *Koro, jinjin bemar, suk yeong, suo-yang* (usually just 'Koro') refers to an acute panic/anxiety reaction to the belief, in a man, that his penis will suddenly withdraw into his abdomen, or in a woman that her breasts, labia or vulva will retract into her body. This is reported in south-east Asia, south China and India. Other examples include *amok, brain fag, dhat,* and *ghost sickness.* These disorders are 'outside' the mainstream of abnormality as defined by, and 'enshrined' within, the classification systems of western psychiatry, which determines the 'standard'. The

underlying assumption is that mental disorders in the West are *culturally neutral,* that they can be defined and diagnosed objectively, while only CBSs show the influence of culture (Fernando, 1991).

Amok – a culture-bound syndrome. But aren't Western mental disorders also influenced by culture?

At the same time, these (and other) cross-cultural studies suggest that the concept of mental disorder isn't merely an expression of western values, but represents a basic human way of perceiving certain behaviour as evidence of abnormal psychological processes. According to Price & Crapo (1999):

> ... mental disorders occur in all cultures ... all cultures appear to label some specific behaviours in a way that is similar to the categories and definitions used by Western psychiatry ...

Problems with the classification of mental disorder

One of the most famous studies criticising basic psychiatric concepts and practices is that of Rosenhan (1973).

KEY STUDY 43.1 On being sane in insane places (Rosenhan, 1973)

- Eight psychiatrically 'normal' people (a psychology student, three psychologists, a paediatrician, a psychiatrist, a painter–decorator, and a housewife) presented themselves at the admissions offices of 12 different psychiatric hospitals in the USA, complaining of hearing voices saying 'empty', 'hollow' and 'thud' (auditory hallucinations).
- These symptoms, together with their names and occupations, were the only falsification of the truth involved at any stage of the study.
- All eight *pseudo-patients* were admitted (in 11 cases with a diagnosis of 'schizophrenia', in the other 'manic depression'), after which they stopped claiming to hear voices. They were eventually discharged with a diagnosis of 'schizophrenia (or manic depression) in remission' (i.e. without signs of illness).
- The only people to have been suspicious of their true identity were some of their 'fellow' patients. It took between 7 and 52 days (average 19) for them to convince the staff that they were well enough to be discharged.
- In a second experiment, members of a teaching hospital were told about the findings of the original study, and were warned that some pseudo-patients would be trying to gain admission during a particular three-month period. Each member of staff was asked to rate every new patient as an impostor or not. During the experimental period, 193 patients were admitted, of whom 41 were confidently alleged to be impostors by at least one member of staff, 23 were suspected by one psychiatrist, and a further 19 were suspected by one psychiatrist and one other staff member. All were genuine patients.

ASK YOURSELF...

- What conclusions can you draw about psychiatric diagnosis from Rosenhan's study?
- Are there any features of the study that would make generalisation difficult?

Rosenhan's study was intended to test the hypothesis that psychiatrists cannot reliably tell the difference between people who are genuinely mentally ill and those who aren't. Since reliability is a necessary prerequisite for validity, the implications of Rosenhan's results for the traditional psychiatric classification of mental disorders are very serious indeed.

Reliability

Diagnosis is the process of identifying a disease and allocating it to a category on the basis of symptoms and signs. Clearly, any system of classification will be of little value unless psychiatrists can agree with one another when trying to reach a diagnosis (*inter-rater/inter-judge reliability*) and represents a fundamental requirement of any classification system (Gelder *et al.*, 1989, 1999).

Early studies consistently showed poor diagnostic reliability. Psychiatrists varied widely in the amount of information they elicited at interview, and in their interpretation of that information, and variations were found between groups of psychiatrists trained in different countries. For example, the US–UK Diagnostic Project (Cooper *et al.*, 1972) showed American and British psychiatrists the same videotaped clinical interviews and asked them to make a diagnosis. New York psychiatrists diagnosed schizophrenia twice as often, while the London psychiatrists diagnosed mania and depression twice as often. (This led some wit to recommend that

American schizophrenics should cross the Atlantic for a cure – presumably, the same advice should be given to British manic–depressives!) However, New York was thought not to be typical of North America.

The 'International Pilot Study of Schizophrenia' (WHO, 1973) compared psychiatrists in nine countries – Columbia, the former Czechoslovakia, Denmark, England, India, Nigeria, Taiwan, USA and the former USSR. It found substantial agreement between seven of them, the exceptions being the USA and USSR, which both seemed to have unusually broad concepts of schizophrenia (thus confirming, after all, Cooper *et al.*'s results).

Improving reliability

- Agreement between psychiatrists can be improved if they're trained to use standardised interview schedules, such as the *Present State Examination* (PSE) (Wing *et al.*, 1974), and Endicott and Spitzer's (1978) Schedule of Affective Disorders and Schizophrenia (SADS). These are intended to:
  - specify sets of symptoms which must be enquired about, and
  - define the symptoms precisely and give instructions on rating their severity.

  As we noted earlier, both DSM and ICD use explicit operational criteria in making a diagnosis, making diagnosis more objective and hence more reliable. These are basically rules for deciding whether a particular patient is to be included within a particular diagnostic category or excluded from it.
- Much more attention is now paid to how symptoms of a given disorder may differ depending on the *culture* in which it appears (see Critical Discussion 43.3). For example, guilt is common in western societies, but rare in Japan or Iran. In the USA, depression among Latinos is more likely to involve *somatic* (bodily) symptoms, such as headaches and 'nerves' than among the white population (Davison *et al.*, 2004). In DSM-IV-TR, cultural differences are dealt with (a) in descriptions of each disorder in the main body of the manual, (b) in an appendix that provides a general framework for evaluating the role of culture and ethnicity, and (c) by describing CBSs in the appendix (see above).
- As far as ICD-10 is concerned, Okasha *et al.* (1993) found higher reliability compared with both ICD-9 and DSM-III-R, and Sartorious *et al.* (1993) concluded that ICD-10's clinical guidelines were suitable for widespread international use and showed good reliability. ICD-10 is expected to remain in use for about 20 years (twice as long as its predecessors) (Costello *et al.*, 1995).

The improved explicitness of DSM criteria has reduced the descriptive inadequacies that were a major source of unreliability in the early editions. The greater overall reliability has been aided by the use of 'decision trees' and computer programs that lead the psychiatrist through each tree (Holmes, 1994). Despite some categories (still) having greater reliability than others, this is now quite acceptable for most of the major categories (Davison *et al.*, 2004). However, problems remain.

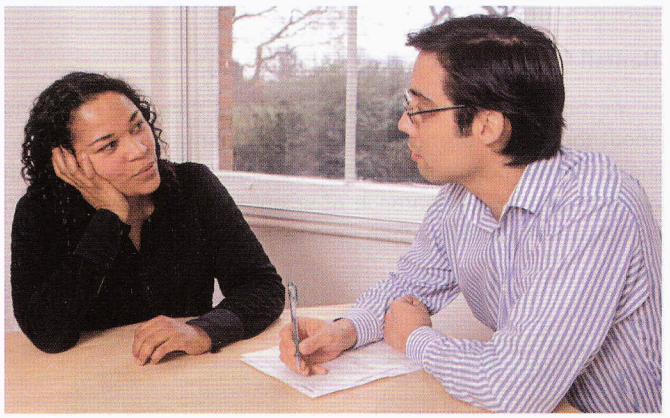
- Specifying a particular number of symptoms from a longer list that must be evident before a particular diagnosis can be made seems very arbitrary. For example, DSM-IV-TR insists on depressed mood plus four other symptoms to be present to diagnose major depression (see Table 44.1, page 786). But why four (Davison *et al.*, 2004; Pilgrim, 2000)?
- The reliability of Axes I and II may not always be as high in everyday practice as they are when psychiatrists know they're taking part in a formal reliability study (Davison *et al.*, 2004).
- There's still room for subjective interpretation on the part of the psychiatrist. For instance, the elevated mood must be 'abnormally and persistently elevated' in order to diagnose mania. Likewise, assessment on Axis V requires comparison between the patient and an 'average person'. These examples beg all sorts of questions. As Davison *et al.* (2004) say:

  > ... Such judgements set the stage for the insertion of cultural biases as well as the clinician's own personal ideas of what the average person should be doing at a given stage of life.

- However, Falek & Moser (1975) found that agreement between doctors regarding angina, emphysema and tonsillitis (diagnosed without a definitive laboratory test) was no better (and sometimes actually worse) than that for schizophrenia. Clare (1980) argues that the nature of physical illness is not as clear-cut as the critics of the medical model claim. While agreeing with criticisms of psychiatric diagnosis, Clare believes these should be directed at psychiatrists and not the process of diagnosis in general.

Validity

This is much more difficult to assess than reliability, because for most disorders there's no absolute standard against which diagnosis can be compared. However much we improve reliability, this is no guarantee that the patient has received the 'correct' diagnosis (Holmes, 1994).



Predictive validity

The primary purpose of making a diagnosis is to enable a suitable programme of treatment to be chosen. Treatment cannot be selected randomly, but is aimed at eliminating the underlying cause of the disorder (where it's known). But in psychiatry there's only a 50 per cent chance of predicting correctly what treatment a patient will receive on the basis of diagnosis (Heather, 1976). Bannister *et al.*

(1964) analysed statistically the relationship between diagnosis and treatment in 1000 cases, and found that there simply was no clear-cut connection. One reason for this seems to be that factors other than diagnosis may be equally important in deciding on a particular treatment.

For example, not only are black people in the UK more likely to be diagnosed as schizophrenic or compulsorily admitted to psychiatric hospital, they're also more likely to be given major tranquillisers or electroconvulsive therapy (ECT) than whites (Fernando, 1988). All ethnic minorities are less likely to be referred for psychotherapy than indigenous whites, and similar differences have been reported between working-class and middle-class groups. Women are also more likely to be diagnosed as psychiatrically ill than men (Winter, 1999: see Chapters 44 and 47). Winter (1999) believes that one viable explanation for these differences is that:

> ... general practitioners and psychiatrists, who are predominantly white, middle class and male, may be biased against, or insufficiently sensitive to the cultural and social situations of, black, working-class or female clients ...

Culture plays a part in all aspects of psychiatric assessment and treatment

Response to treatment is also difficult to predict (see Chapter 45: Winter, 1999).

Construct validity

This is the most relevant form of validity in relation to diagnosis. According to Davison *et al.* (2004), the categories are *constructs* because they're *inferred* – not proven – entities. For example, a diagnosis of schizophrenia doesn't have the same status as a diagnosis of, say, diabetes. With physical disease, there's a real sense in which patients 'have' it, and it's feasible to distinguish them from their disease. But even in the more extreme psychotic states, it's impossible to divorce the condition from the person (Marzillier, 2004).

Construct validity is determined by evaluating the extent to which accurate statements and predictions can be made about a category. For example, to what extent does the construct form part of a network of lawful relationships? These relationships could concern:

- possible causes (such as genetic predisposition or biochemical imbalance: see Chapter 44)
- characteristics of the disorder that aren't symptoms as such, but are associated with the disorder (such as poor social skills in schizophrenia)
- predictions about the course of the disorder and probable response to particular treatments (see above).

Davison *et al.* believe that the DSM diagnostic categories do indeed possess some construct validity – some more than others. However, according to Mackay (1975):

> The notion of illness implies a relatively discrete disease entity with associated signs and symptoms, which has a specific cause, a certain probability of recovery and its own treatments. The various states of unhappiness, anxiety and confusion which we term 'mental illness' fall far short of these criteria in most cases.

Pilgrim (2000) argues that calling madness 'schizophrenia', or misery 'depression' merely *technicalises* ordinary judgements. What do we add by calling someone who communicates unintelligibly 'schizophrenic'? Similarly, Winter (1999) argues that:

> ... diagnostic systems are only aids to understanding, not necessarily descriptions of real disease entities ...

CONCLUSIONS: TO CLASSIFY OR NOT TO CLASSIFY?

ASK YOURSELF...

- Do you think it's scientifically valid – and ethically acceptable – to categorise people in terms of mental disorders?

The case for

- Classifications are needed in psychiatry, as in medicine, to aid communication about the nature of patients' problems, prognosis and treatment. It obviously helps when exchanging information about individual cases if there's some agreed terminology available and if a label can be assigned that distinguishes one patient's disorder from another's (Claridge & Davis, 2003; Gelder *et al.*, 1989).
- Assuming that various types of abnormal behaviour do differ from one another, classifying them is essential, for these differences may provide vital clues to their causes and treatments (Claridge & Davis, 2003; Davison *et al.*, 2004). Classification allows research to be conducted with comparable groups of patients (Gelder *et al.*, 1989).

The case against

- The very fact that there are different classification schemes (DSM and ICD are the most commonly used

and cited, but aren't the only ones) demonstrates that there's a certain degree of arbitrariness about how people are diagnosed. DSM-IV-TR and ICD-10 merely represent the *current* (or most recent) beliefs of experts in the field about how psychological disorders should be classified.

> ... the fact that they [DSM and ICD] are not identical indicates that the diagnostic categories they suggest are somewhat arbitrary and often represent compromise. This is bound to be the case, since the contents of both merely result from decisions made in committee by groups of professionals, experienced in their own fields, but often of differing theoretical persuasion or clinical expertise ... (Claridge & Davis, 2003)

These limitations relate to the *validity* of classification (see above).

- Similarly, the fact that DSM has undergone several revisions confirms the *constructive* nature of attempts to classify psychological disorders. As Critical Discussion 43.1 shows, psychiatrists can, and do, change their views regarding what should count as a disorder in response to wider social and cultural changes. Critical Discussion 43.2 shows, in addition, that psychiatry reflects fundamental social *values*. In both these ways, classification can never be completely objective or based on science alone. DSM-V is (tentatively) scheduled for 2010 (Bentall, 2003), illustrating the continual 'tweaking' of definitions of psychological disorders. How objective is that?
- Classifying someone as depressed or anxious produces a loss of information about the person, thereby reducing some of his/her uniqueness. Even being a 'former mental patient' may have stigmatising effects on the individual: friends and relatives might treat them differently and work may be hard to find (Davison *et al.*, 2004).
- A central problem for DSM in particular, and classification of disorders in general, is the tendency for an individual to meet the diagnostic criteria for *more than one disorder* (*comorbidity*). This is well documented in medicine, but in these cases the two illnesses/conditions have quite separate aetiology and they *look* very different. But in psychiatry, comorbid disorders often seem surprisingly similar, as though they share a common cause and underlying mechanism (Claridge & Davis, 2003).
- Another major problem is the *overlap* between the symptoms of 'different' disorders. In DSM-IV-TR, several Axis I disorders are descriptively similar to, and have their apparent counterpart in, an Axis II disorder (for example, *obsessive compulsive disorder* (OCD) and *OCD personality disorder*). To consider these as belonging to two totally different categories of abnormality looks very artificial (Claridge & Davis, 2003).

Categories vs dimensions

As we've seen, the classification of mental disorders is *categorical*. Abnormality is assumed to differ qualitatively from normality, so that a person either belongs in a particular category or doesn't. But some researchers have argued that the most appropriate system for diagnosing and assessing mental disorders is *dimensional;* abnormality and normality are only *quantitatively* different (involving a *continuum* of severity: Lilienfeld, 1998).

These two approaches mirror the important difference between psychiatry and psychology. According to Pilgrim (2000), diagnosis is a medical task that creates a simple dichotomy between the sick and the well: 'Is this person suffering from a mental disorder or not?' (and by extension, if 'yes', 'which one?'). By contrast, psychologists assume a *continuity* between normal and abnormal: 'How do we account for this person's actions and experience in this particular context?' According to Marzillier (2004):

> ...The experiences that lead people to be diagnosed as 'mentally ill' are experiences that all of us can have in some form or at some stage ...

Bentall (2003) argues that:

> ... we have been labouring under serious misunderstandings about the nature of madness for more than a century, and ... many contemporary approaches to the problem, although cloaked with the appearance of scientific rigour, have more in common with astrology than rational science ...

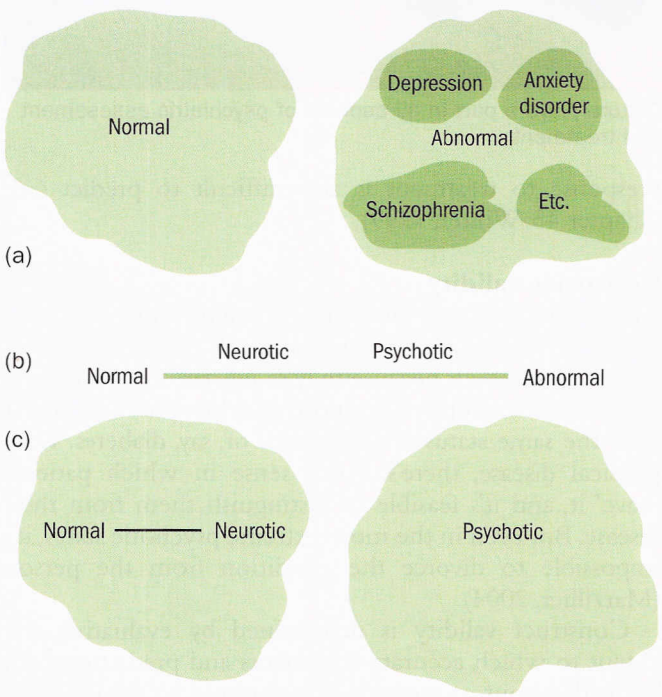


Figure 43.3 Representations of (a) the categorical and (b) the dimensional views of abnormality. (c) combines (a) & (b)

Two of these serious misunderstandings or false assumptions are, first, that madness can be divided into a small number of diseases and, second, that the manifestation or 'symptoms' of madness cannot be understood in terms of the psychology of the person who suffers from them.

Gelder *et al.* (1989) believe that:

> The use of classification can certainly be combined with consideration of a patient's unique qualities, indeed it is important to combine the two because these qualities can modify prognosis and need to be taken into account in treatment ...

In other words, the categorical and dimensional approaches aren't necessarily incompatible. Figure 43.3c suggests how they might be combined.

According to Davison *et al.* (2004), early indications are that DSM-V will become *more dimensional* than categorical.

CHAPTER SUMMARY

- Abnormality as **deviation from the average** (the **statistical criterion**) defines abnormality as not behaving in the way that most people do. But this fails to distinguish between atypical behaviour that's desirable and undesirable.
- **Deviation from the norm** defines abnormality as not behaving or feeling as one is **expected** to. But it's not obvious what norms are being broken in the case of mental disorder.
- The **deviation from ideal mental health** criterion identifies several definitions of mental health. But these involve **value judgements** about ideal states that are culturally defined (unlike physical health).
- Abnormality as **personal distress/suffering** defines abnormality in terms of subjective experiences. **Other people's distress** may act as a counterbalance to the lack of insight shown by some people with a mental disorder.
- Abnormality as **maladaptiveness** focuses on the **consequences** of abnormal behaviour for the individual, especially being prevented from achieving one's goals.
- Abnormality as **unexpected behaviour** means overreacting to something, but underreacting could be considered just as abnormal. Behaviour that's highly **consistent/predictable** or **highly inconsistent/unpredictable** may be considered abnormal.
- The way we talk about psychological disorder reflects the **medical model**. Critics argue that the norms from which the mentally ill are thought to deviate are expressed in moral, psychological and legal terms, not medical ones, yet the solution takes the form of medical treatment.
- According to Scheff, schizophrenics are breaking **residual rules**, which tend to reflect middle-class values regarding 'decency' and 'reality'.
- According to Szasz, individuals diagnosed as mentally ill either have **neurophysiological** disorders (corresponding to **organic psychosis**) or, more often, **problems in living** (corresponding to **functional psychosis**). This makes the concept of *mental* illness meaningless.
- An integral part of the medical model is the **classification** of mental disorder and the related process of **diagnosis**. All systems of classification stem from Kraepelin's identification of *dementia praecox* (schizophrenia) and manic–depressive psychosis.
- **DSM-IV-TR** uses a larger number of discrete categories to classify mental disorders that appear under a smaller number of wider categories in **ICD-10**.
- DSM uses a **multi-axial system** of classification, representing different areas of functioning: **clinical syndromes** (Axis I); **personality disorders/mental retardation** (Axis II); **general medical conditions** (Axis III); **psychosocial and environmental problems** (Axis IV); and **global assessment of functioning** (Axis V).
- ICD doesn't have separate axes in the way that DSM does, but broad types of **aetiology** are built into the categories of mental disorder. DSM makes no assumptions about aetiology and is **atheoretical**.
- Both DSM and ICD have dropped the traditional distinction between **neurosis** and **psychosis**. Psychosis is a much more serious form of mental disorder, due to loss of contact with reality, and is **qualitatively different** from 'normal' behaviour.
- The **cross-cultural** study of schizophrenia tries to determine whether it's **absolute** ('culture-free'), **universal** or **culturally relative**. Culture can influence the form of symptoms, precipitating events for the onset of symptoms, and prognosis.
- **Culture-bound syndromes** (CBSs) are seen as falling outside mainstream classifications of disorder, implying that western mental disorders are objective and uninfluenced by cultural factors. However, all cultures seem to have the concept of mental disorder.
- **Inter-rater/judge reliability** has been improved in more recent versions of both DSM and ICD by the use of **standardised interview schedules** and **explicit diagnostic criteria**. But there's still room for subjective interpretation.
- **Validity** is more difficult to assess in the absence of absolute standards. For a diagnosis to be considered valid, it should allow prediction of treatment and recovery, as well as implying the cause(s) of the disorder.
- Psychotherapists using an **idiographic approach** criticise the use of psychiatric classification (which adopts a **nomothetic**, **categorical** approach), and psychologists prefer a **dimensional approach**. But these two approaches aren't mutually exclusive.

Links with other topics/chapters

- The concepts of *health, illness* and *disease* are central to *health psychology* (Chapter 12).
- In the context of definitions of abnormality, *helping* the 'patient' could be motivated either by an *altruistic* desire to end his/her distress, or by an *egoistic* desire to end the helper's own distress. This distinction applies to *bystander intervention* and other forms of *prosocial behaviour* (Chapter 30).
- The attribution of blame and responsibility (denied to the mentally ill) (Chapter 23) is relevant to understanding why certain types of *victim* are more or less likely to be *helped* (Chapter 30).
- Szasz's argument, that only the brain can literally be diseased, and not the mind, breaks down if we *identify the mind with the brain* (Chapter 49).
- Axis IV of DSM-IV-TR relates to *life changes* as measured by Holmes and Rahe's (1967) *Social Readjustment Rating Scale* (SRRS) (Chapter 12).
- The idea that schizophrenia might be found in all cultures in precisely the same form ('culture-free') corresponds to the belief that it's possible to construct *culture-free tests of intelligence* (Chapter 41).
- While *cross-cultural psychology* looks for *universal* aspects of human behaviour, *cultural psychology* focuses on how behaviour *differs* between cultures (*cultural relativism*) (Chapter 47).
- Regular revisions of DSM and other classification systems have a parallel in the *scientific revolutions* (involving *paradigm shifts*) described by Kuhn. Both illustrate the *social nature of scientific activity* (Chapter 3).
- Eysenck is largely responsible for introducing the dimensional approach to abnormality through his *theory of personality* (Chapter 42).
- The categorical system adopts a *nomothetic* approach: it emphasises the similarities between people (what all schizophrenics, for example, have in common). Its critics consider that an *idiographic* approach is more appropriate (Chapter 42).

PSYCHOPATHOLOGY

INTRODUCTION AND OVERVIEW

As we saw in Chapter 43, the classification of mental disorders is an integral part of the *medical model*. ICD-10 (1992) and DSM-IV-TR (2000) identify several general categories of mental disorder, within each of which are found a number of specific disorders. This chapter samples some of the disorders which, both historically and currently, have attracted most research interest – and often the most debate and controversy, both within and outside psychiatry.

Anxiety disorders are a category in DSM subsumed by the ICD category *neurotic, stress-related and somatoform disorders.* These include *phobic disorders* (*phobic anxiety disorders* in ICD), *obsessive–compulsive disorder* (OCD), and *post-traumatic stress disorder* (PTSD).

Eating disorders are a DSM category subsumed by ICD's *behavioural syndromes associated with physiological disturbances and physical factors.* Two major eating disorders are *anorexia nervosa* and *bulimia nervosa.*

Of all the disorders identified in ICD and DSM, *schizophrenia* is the most serious. Kraepelin (1913) called the disorder *dementia praecox* (senility of youth), believing that it occurred early in adult life and was characterised by a progressive deterioration or dementia. However, Bleuler (1911) observed that it also began in later life, and wasn't always characterised by dementia. Bleuler coined the word 'schizophrenia' to refer to a splitting of the mind's various functions, in which the personality loses its unity.

Mood (or *affective*) *disorders* involve a prolonged and fundamental disturbance of mood and emotions. At one extreme is *manic disorder* (or *mania*), and at the other is *depressive disorder.* Mania usually occurs in conjunction with depression (*bipolar disorder*). The term *unipolar* is reserved for the occurrence of depression on its own. (The term *manic–depressive* refers to *both* the unipolar and bipolar forms of affective disorder.)

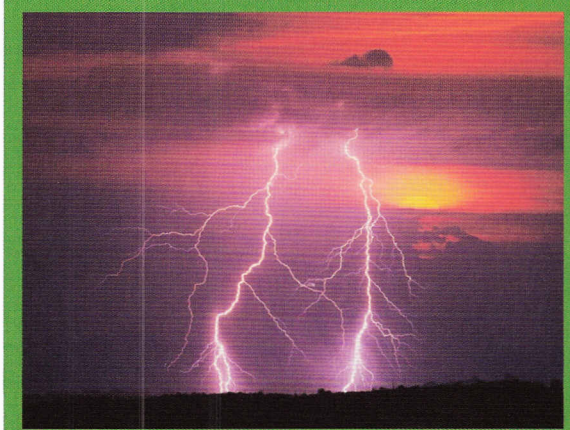
ANXIETY DISORDERS

Of all forms of psychological distress, emotional disturbances are perhaps the most common (Lilienfeld, 1998), and 'fear is a core emotion in psychopathology' (LeDoux, 1998). While anxiety (a brooding fear of what might happen) was a central feature of Freud's psychoanalytic theory (LeDoux, 1998), many psychologists have argued that fear is a fundamentally *adaptive reaction* to stressors (specifically, threat). It's generally considered abnormal only when it's disproportionate to objective circumstances. Fear probably evolved as an alarm signal to warn organisms of potential danger. But some people tend to feel afraid even when there's no (objective) threat present: these 'false alarms' are what we call anxiety disorders.

For example, people with *panic disorder* experience sudden surges of extreme terror, even in perfectly safe environments. As Lilienfeld (1998) says:

> ... it is this mismatch between the severity of individuals' emotional reactions and of objective stressors that makes panic disorder psychopathological ...

ASK YOURSELF...



- While this might seem like a perfectly reasonable way of distinguishing normal from abnormal anxiety, can you see any flaws in the argument?
- How does it relate to the categorical/dimensional approaches discussed in Chapter 43? (See pages 772-773.)

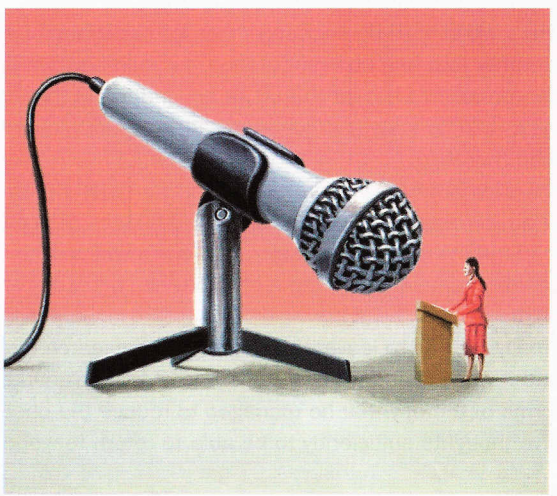
Phobic disorders

A *phobia* is an extreme, *irrational* fear of some specific object or situation. Typically, the patient acknowledges that the object of fear is harmless, but the fear is experienced nonetheless (this is the irrational element). Trying to avoid the feared object or situation at all costs can interfere with the person's normal functioning, and distinguishes a phobia from a milder fear or mere dislike of something. Attempts to hide the phobia from others may induce further anxiety, guilt, and shame.

Box 44.1 The variety of phobias

Acrophobia: high places
Algophobia: pain
Anthropophobia: men
Aquaphobia: water
Arachnophobia: spiders
Astraphobia: storms, thunder, lightning
Belonophobia: needles
Claustrophobia: enclosed spaces
Cynophobia: dogs
Hematophobia: blood
Neophobia: anything new
Nycotophobia: the dark
Octophobia: the figure eight
Ophidiophobia: snakes
Opthalmophobia: being stared at
Paraphobia: sexual perversion
Pathophobia: disease
Phobophobia: phobias
Phonophobia: noises/voices
Pyrophobia: fire
Sclerophobia: bad men/burglars
Sociophobia: society/people in general
Technophobia: digital/computer technology
Thanatophobia: death
Xenophobia: strangers

Astraphobia



As Box 44.1 shows, almost anything may become the object of a phobia, but some phobias are much more common than others. DSM-IV-TR identifies three categories of phobia: *agoraphobia* (without history of panic disorder), *social phobia,* and *specific phobias.*

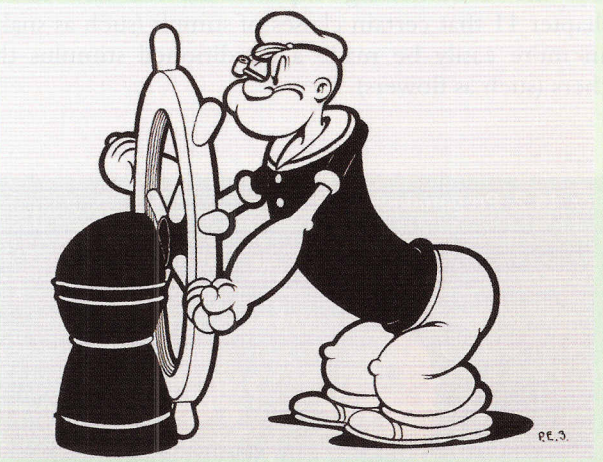
Agoraphobia

This is the most common of all phobias (accounting for about 60 per cent of all phobic patients), and occurs predominantly in women (while most other phobias tend to be fairly evenly divided between the sexes). While agoraphobia is commonly defined as fear of open spaces, the *primary* fear is leaving the safety and security of home and/or companions. Fear of being in public places is *secondary* but, significantly, this is what the patient is usually aware of. It often centres on a fear of finding oneself in a situation from which escape is difficult, or where help is unavailable in the event of a panic attack (which often accompanies agoraphobia). Indeed, nearly all researchers agree that all cases of agoraphobia stem from fear of panic attacks (Lilienfeld, 1998). Mitchel (1982) sees agoraphobia as a form of separation anxiety (see Chapter 32).

Social phobia

This was identified in the UK in 1970, but not included in DSM until 1980 (Menninger, 1995). It's an intense and excessive fear of being observed by other people, such as when eating or drinking in public, talking to members of the opposite sex, or having to speak or write in front of others. These are all examples of *performance* social phobia. *Limited interactional* social phobia involves feeling anxious only in specific situations (such as when interacting with an authority figure), while *generalised* social phobia arises in most social situations.

Having to make a speech in front of any kind of audience is likely to induce some degree of anxiety in most people. As a social phobia, anxiety over public speaking is an intense and excessive fear of being exposed to scrutiny by other people; it's an example of performance social phobia



The underlying fear is of acting in a way that's embarrassing or humiliating for the self or others. Like agoraphobia, most social phobics are women, and the problem typically begins in adolescence.

Specific phobias

Most phobias fall into this category (see Box 44.1), and definitions of phobias usually relate to specific phobias. Generally, these are less disruptive than agoraphobia or social phobias. They can develop at any time of life, although some are quite common in childhood (such as cynophobia and nycotophobia), while 'illness and injury' phobias (and thanatophobia) tend to occur in middle age.

CASE STUDY 44.1 Popeye phobia

A three-year-old girl suddenly developed recurrent bronchitis, which got worse when she attended nursery school. The trouble was traced to the slippers of a boy in the same class. Every time the girl saw them she began to retch and cough, and became upset. The slippers sported a picture of Popeye, the cartoon sailor man. Even the mention of his name induced coughing. The girl had seen a Popeye cartoon at her friend's house and became frightened of it. Following behaviour therapy (see Chapter 45), the girl recovered.

(Based on Murray, 1997)

Explaining phobias

ASK YOURSELF...

- How would Freud account for phobias (see Chapter 43)?
- How would learning theory explain them (see Chapter 11)?

According to Freud, phobias are the *surface* expression of a much deeper conflict between the id, ego and superego,

originating in childhood (as in Little Hans' fear of horses: see Chapter 35, page 605). Phobias are (conscious) expressions of (unconscious) unacceptable wishes, fears, and fantasies that have been *displaced* from their original, internal source onto some external object or situation that can be easily avoided.

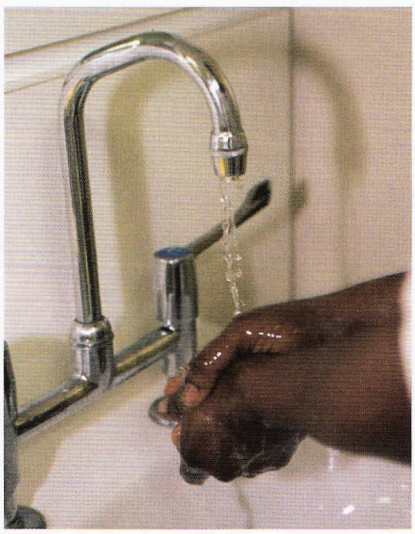
Behaviourist critics of Freud's explanation pointed out that Hans's phobic response only occurred in the presence of a large horse pulling a heavily loaded cart at high speed, and that the phobia developed *after* Hans had witnessed a terrible accident involving a horse pulling a cart at high speed. As we saw in Chapter 11, phobias can be classically conditioned, and Wolpe (1969) argued that this is how *all* phobias arise. Some phobics (but not all) trace their phobias to some traumatic experience (often in childhood).

According to Mowrer's (1947) *two-process/two-factor theory,* phobias are *acquired* through classical conditioning (factor 1) and *maintained* through operant conditioning (factor 2): *avoidance* of the phobic stimulus and the associated reduction in anxiety is *negatively reinforcing.* By contrast, Rachman's (1984) *safety signal hypothesis* sees avoidance as being motivated by *positive* feelings of safety. However, the fact that some phobics cannot recall any traumatic experiences, and that extreme trauma doesn't inevitably lead to a phobia developing, is inconsistent with the conditioning explanation. We also saw in Chapter 11 that certain classes of stimuli (such as snakes) can more easily be made a conditioned stimulus than others (such as flowers).

Box 44.2 Preparedness

- Rosenhan & Seligman (1984) propose an *interaction* between biological and conditioning factors that predisposes us to acquire phobias of certain classes of stimuli.
- According to the concept of *preparedness/prepared conditioning*, we're genetically prepared to fear things that were sources of danger in our evolutionary past (see Gross *et al.*, 2000).
- Hugdahl & Ohman (1977) have shown that in laboratory experiments, people without pre-existing phobias can be conditioned more easily to snakes than flowers.
- However, snakes have a negative 'reputation' or social status, while flowers are generally viewed positively and are completely non-threatening. So, although preparedness as an explanation for direct conditioning may not be valid, preparedness for *observational and instructional learning* is possible (Murray & Foote, 1979; Rachman, 1977).

Obsessive-compulsive disorder (OCD)



Obsessions are recurrent, unwanted, intrusive thoughts or images that don't feel voluntarily controlled, and which are experienced as morally repugnant or intensely distressing. They mostly have sexual, blasphemous, or aggressive themes (see Case Study 44.2). For example, it's not uncommon for deeply religious people to have repeated blasphemous thoughts, such as 'God doesn't exist', or for caring parents to have thoughts of harming their children. These obsessions are resisted by being ignored or suppressed, or by 'neutralising' them with some other thought or action (Shafran, 1999); these may include compulsions.

CASE STUDY 44.2 Obsession without the compulsion (Sutherland, 1976)

- An example of an obsession occurring without compulsive behaviour is sexual jealousy, an extreme case of which is described by Stuart Sutherland in *Breakdown* (1976).
- Sutherland was a well-known British experimental psychologist who'd been happily married for several years when his wife suddenly revealed she'd been having an affair (but had no wish to end their marriage). At first, he was able to accept the situation, and found that the increased honesty and communication actually improved their marriage.
- However, after asking his wife for further details of the affair, he became obsessed with vivid images of his wife in moments of sexual passion with her lover, and he couldn't remove these thoughts from his mind, day or night.
- Finally, he had to leave his teaching and research duties, and it was only after several months of trying various forms of therapy that he managed to reduce the obsessive thoughts sufficiently to be able to return to work.

Compulsions are actions which the victim feels compelled to repeat over and over again, according to rituals or rules. Obsessions and compulsions are often related, the latter representing an attempt to counteract the former. For

example, compulsive handwashing may be an attempt to remove the obsessive preoccupation with contamination by dirt or germs, either as agent or victim. While the person recognises that the compulsive act is unreasonable and excessive, it's also seen as purposeful. The function of compulsive acts is to prevent a dreaded event and reduce distress. Many patients find the need to perform the compulsion distressing in itself, and are frustrated by the time it takes to complete it 'correctly' and how it interferes with normal social and work functioning.

Compulsive hand-washing is often an attempt to remove an obsessive preoccupation with contamination

Shafran (1999) gives the example of a man who was obsessed with the thought that he'd contracted AIDS from sitting next to someone who looked unkempt. In response to this, he repeatedly checked his body for signs of illness and washed his hands whenever he had an intrusive image of this person. When outside, he'd continually check around him to see if there were any discarded tissues that might carry the HIV virus. This became so laborious that he stayed indoors for much of the time. Any interruption to the checking and washing resulted in the entire routine starting again.

Until quite recently, OCD was regarded as a rare disorder (affecting less than 0.5 per cent of the population). Now, however, it's the fourth most common disorder, and lifetime prevalence is at least 3 per cent in females and 2 per cent in males. In the UK, an estimated one to one-and-a-half million people suffer from OCD. According to Claridge & Davis (2003), it's still often under-diagnosed and under-treated in most populations. Between a third and a half of patients experienced their first symptoms during childhood, but it mostly goes unnoticed then. It usually begins in early adulthood, but begins earlier in males. Women have more contamination and aggressive obsessions, and tend to display more cleaning rituals. Men's obsessions are more likely to concern symmetry and order, exactness and sex, and they're most likely to be hoarders (see below).

Some issues regarding classification and diagnosis

- Some writers have questioned whether OCD should be classified as an anxiety disorder at all. Indeed, in ICD-10 it's listed separately from anxiety disorders. Others have suggested that anxiety is a *product* of the distressing and disabling symptoms (*not* a cause).
- Like other disorders, OCD's clinical features are *heterogeneous:* individuals with OCD may differ considerably from one another. Any one individual may have one (but typically several) of a variety of symptoms, in varying degrees and combinations. Earlier attempts to deal with this variability led to the identification of 'washers' and 'checkers'. It was thought that all patients fell into one or other category, but now there are at least four or five recognised primary dimensions: *symmetry and ordering, hoarding, contamination and cleaning, aggressive obsessions and checking,* and *sexual and religious obsessions* (Claridge & Davis, 2003).
- OCD has always been firmly embedded within the 'neurotic' disorders (see Chapter 43). This is because of the assumption that patients recognise the excessive and unreasonable nature of their obsessions and compulsions (they have *insight*). But OCD patients display varying degrees of insight, and in about 10 per cent of cases they seem to lack it altogether. Their thinking begins to resemble *delusions* (which are more 'psychotic'), and they may be diagnosed as 'schizophrenic', 'psychotic–schizo-affective subtype' or 'delusional disorder or psychotic disorder not otherwise specified' (Claridge & Davis, 2003). A key factor that distinguishes OCD patients with delusions from psychotics is the clear and logical link between the OCD patient's delusional thoughts and the compulsions they induce (O'Dwyer & Marks, 2000).

Box 44.3 Body dysmorphic disorder (BDD)

- Morselli (1886) introduced the term *dysmorphophobia* (from the Greek *dysmorphia,* meaning 'ugliness of the face'), defining it as the subjective feeling of ugliness and of a physical defect, despite a normal appearance, and an associated feeling of shame.
- It was first called *body dysmorphic disorder* in DSM-III-R (1987), and appears in both DSM-IV-TR and ICD-10, where it's classified as a hypochondriacal disorder. But according to Sobanski & Schmidt (2000), some recent researchers have classified it as an 'obsessive-compulsive spectrum' disorder. The characteristic feature is an intense preoccupation with an imagined or real, but minor, defect of physical appearance. This concern becomes so overwhelming that it causes clinically significant distress and impairment in social, occupational and other important areas of functioning.

- Any part of the body can be involved, but most commonly anxiety centres on the face and hair abnormalities – like thinning hair or fear of going bald. Unlike patients with eating disorders (see text below, pages 800–805), BDD patients don't have a disturbed body image as a whole. Their preoccupations are often experienced as repetitive, intrusive thoughts associated with anxiety and distress (as in OCD).
- Most BDD patients perform ritualised behaviours resembling OCD compulsions, such as mirror-checking, grooming behaviours and compulsive skin-picking.
- BDD is treated using psychoactive drugs and psychological therapies. But some patients elect to have cosmetic surgery. Typically, the initial feelings of happiness are replaced by a shifting of their symptoms to another body part, some patients undergoing up to nine operations (Simeon *et al.*, 1995; Veale *et al.*, 1996).
- For example, Helen, a woman of uncommon beauty, became convinced as a teenager that her nose was repugnantly small. After three separate cosmetic surgical procedures, she still viewed her nose as misshapen. Two years of psychotherapy failed to help her, and she eventually responded to clomipramine (Anafranil: see Chapter 45) (Bower, 1995).

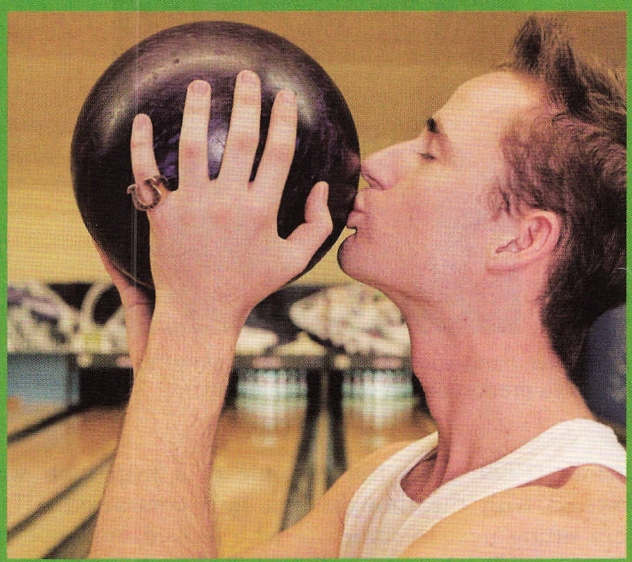
Explaining OCD

Behavioural explanations

ASK YOURSELF...

- How might you explain OCD in terms of conditioning principles? (See Chapter 11.)

A *behavioural* explanation would see OCD as a way of reducing anxiety. If an obsession induces anxiety, then any compulsive behaviour that alleviates the anxiety should be more likely to occur (through *negative reinforcement:* e.g. Rachman & Hodgson, 1980). Since the compulsion provides only *temporary* relief from anxiety, when it starts to increase again the person is motivated to repeat the compulsive act. Paradoxically, compulsions (as well as avoidance and trying to suppress the obsession) serve to *increase* the frequency of the obsession. As Shafran (1999) says:



> These obsessions subsequently increase the compulsive behaviour, leaving the person trapped in the vicious obsession–compulsion cycle ...

An evaluation of behavioural explanations

◎ The account given above can only account for OCD's *maintenance* – not how it developed in the first place. The *superstition hypothesis* might be more relevant here.

Box 44.4 The superstition hypothesis

- Skinner (1948a) argued that what we call 'superstition' develops as a result of a chance association between some behaviour and a reinforcer.
- In Skinner's experiments, pigeons were given food at regular intervals regardless of their behaviour. After a while, they displayed idiosyncratic movements, presumably because these were the movements they happened to be making when the food was given.
- This chance reinforcement of behaviour can account for many compulsive rituals (O'Leary & Wilson, 1975). For example, the rituals of soccer players may include being last on to the pitch, or wearing only a particular pair of boots. Such behaviours may occur because in the past they were associated with success. If such rituals aren't enacted, anxiety is aroused.

The 'lucky kiss', a common form of superstitious behaviour among sportsmen and women

- However, while such chance associations might explain how particular *behaviours* arise, the development of *intrusive thoughts* are much more difficult to explain by the behavioural model.

◎ Rachman and Hodgson's account explicitly proposed that it's normal for people to have intrusive thoughts. For example, it's been shown that 90 per cent of non-patients have unwanted, intrusive thoughts with the same content as those of people diagnosed with OCD (including the impulse to disrupt a peaceful gathering and to jump in front of an approaching train). However, non-patients can dismiss their obsessions more easily, they experience them less often, and they're less distressed by them (Shafran, 1999). This is related to *interpretation* and *psychological vulnerability* (Salkovskis, 1985: see below).

Cognitive–behavioural explanations

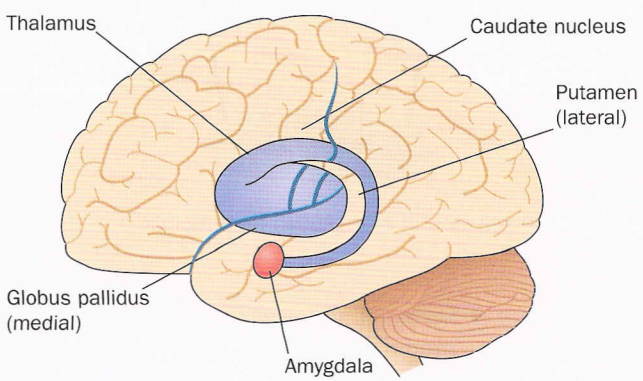
According to *cognitive–behavioural theory* (e.g. Beck, 1976), 'normal' obsessions become abnormal when people interpret the occurrence and content of unwanted intrusive thoughts as indicating that they may be/have been/come to be *responsible* for harm or its prevention (Salkovskis, 1985; Salkovskis *et al.*, 1998). Lopatka & Rachman (1995) showed that in a high-responsibility condition, people with checking compulsions had stronger urges to check, experienced greater discomfort, and made higher estimates of the probability of harm, than those in a low-responsibility condition.

Another interpretation with specific implications for treatment (and which is closely linked to perceived responsibility for harm) is 'thought–action fusion' (TAF) (Rachman, 1993). This involves appraising intrusive thoughts as equivalent to actions. For example, one woman believed that if she had an image of her daughter lying dead, then it was as though she were 'tempting fate' and increasing the chances that her daughter would die. TAF involves two components:

1. *likelihood TAF:* the belief that thinking about an unacceptable or disturbing event makes it more likely actually to happen
2. *moral TAF:* interpreting the obsessive thoughts and forbidden actions as morally equivalent. The person feels that his/her unacceptable thoughts, images and impulses are (almost) as bad as the event (e.g. 'Only a wicked mother would have thoughts about harming her child').

TAF represents a form of *psychological vulnerability,* which increases the likelihood of *misinterpretation* taking place.

An evaluation of cognitive–behavioural explanations



- According to Nieboer (1999), what Rachman calls TAF can be attributed to Freud (1909): patients with OCD had difficulties distinguishing thoughts from actions. If Freud was correct in believing that obsessions are defensive psychological responses, then attempts to prevent compulsive behaviour would, at best, produce *symptom substitution* (see Chapter 45), and at worst, cause psychotic breakdown. Rachman's TAF has implications for the origin, maintenance, and treatment of OCD, which are completely different from those drawn by Freud (Shafran & Salkovskis, 1999).
- This currently popular theory sees OCD as an extension or exaggeration of normal behaviour. One of its great strengths is that it can explain OCD symptoms in terms of everyday, 'normal' cognition and behaviour, as noted below.
  (a) Unwanted or intrusive thoughts may be the precursor to, or raw material of, obsessions. But, more importantly, they're part of everyday cognitive experience. Normal intrusive thoughts in healthy individuals are ideas, impulses and images that interrupt our *stream of consciousness.* Their *content* is indistinguishable from the obsessional thoughts of people with OCD – but they're less intense, less long-lasting and less distressing.
  (b) Similarly, repetitive behaviours are especially common in childhood. This reflects the young child's strong need for predictability and order. Most normal childhood rituals (often fear-related and observable at night time) have disappeared by puberty. But the *extent* of (developmentally normal) childhood compulsions is highly correlated with anxiety.
- What turn normal intrusive thoughts into obsessions are *misinterpretation* and *vulnerability.* Misinterpretation may involve seeing some commonplace object or situation as a potential catastrophe, taking an intrusive thought to be much more personally relevant or threatening than it 'really' is. As we saw above, vulnerability is related to TAF.

ASK YOURSELF...

- How does this evaluation of cognitive behavioural explanations relate to the debate about the categorical vs dimensional approaches to defining abnormality? (See Chapter 43, pages 772–773.)

Biological explanations

(a) Brain neuropathology: Encephalitis, head injuries and brain tumours are all associated with the development of OCD (Jenike, 1986). Several models of OCD all predict, in one way or another, the involvement of the *prefrontal cortex* (PFC), the *basal ganglia* and the *limbic system.* The basal ganglia comprise the caudate, putamen, globus pallidus and the amygdala, and are linked to the control of motor behaviour. The focus on the basal ganglia is due to their relevance to compulsions, as well as the relationship between OCD and Tourette's syndrome. The vocal and motor tics characteristic of Tourette's are linked to basal ganglia dysfunction, and Tourette's patients also often have OCD (Sheppard *et al.*, 1999).

The basal ganglia

The PFC has direct links with the basal ganglia via its connections with the limbic system. It also receives signals *from* these sub-cortical structures. So, there are connections between the PFC and the sub-cortical areas that pass through the limbic system.

According to Saxena *et al.* (1998), the function of all the *direct* pathways between the PFC and basal ganglia is to execute 'pre-packaged', complex responses to 'socioterritorial' stimuli. These refer to things that are highly significant to the organism's survival (such as hygiene, sex, safety, keeping things in order). They need to be performed quickly in order to be adaptive, and must operate to the exclusion of other interfering stimuli. The activation of these direct pathways tends to pin or rivet the execution of the behaviour until the attentional need to do so has passed.

Part of the function of the *indirect* pathways is to inhibit or suppress the direct pathways when it's appropriate to switch to another behaviour. This is something that OCD patients have trouble doing.

Normally, socioterritorial concerns pass through the direct pathway and are inhibited by the indirect pathway relatively quickly. But in OCD patients, excess activation of the direct pathway causes fixation with these concerns. The indirect pathway is too weak to 'turn off' the signal from the direct pathway, and the socioterritorial concerns are experienced by the individual as repetitive, intrusive obsessions.

So, Saxena *et al.*'s model proposes a substantial *imbalance* between the direct and indirect pathways. This causes a response bias towards socioterritorial stimuli.

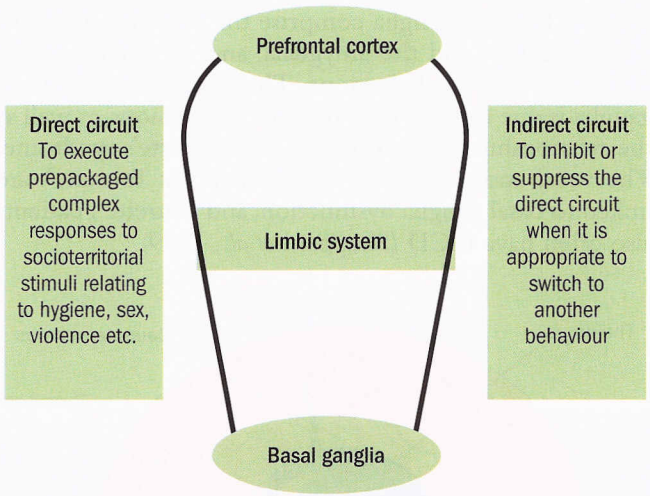


Figure 44.2 Saxena *et al.*'s (1998) model of OCD

An evaluation of Saxena et al.*'s model*

- This popular model meshes well with neurobiological evidence from various sources (Claridge & Davis, 2003). For example, brain imaging studies have consistently shown *increased* activity in the PFC (usually involving the right orbitofrontal cortex) in unmedicated OCD individuals (they display 'overheated' frontal lobes). These hyperactive areas tend to become normal when patients receive effective treatment (either drug therapy or behavioural therapy).
- Rauch *et al.* (1994) stimulated OCD symptoms by presenting patients with stimuli especially selected for them (such as a glove contaminated with household rubbish). This produced increased blood flow in the PFC and certain regions of the basal ganglia. Also, OCD patients have a smaller putamen than controls (Rosenberg *et al.*, 1997).
- The PFC plays an important role in assessing the behavioural significance of biologically important stimuli. So increased frontal lobe activity may relate to obsessional thinking – but not necessarily to compulsions. But the basal ganglia (and cerebellum, which stores behavioural programs, such as conditioned responses) may function to control compulsive urges. People with diseases involving pathology of the basal ganglia (such as Parkinson's and Huntingdon's disease) often show compulsive symptoms similar to those of OCD patients.

(b) The serotonin hypothesis (SH): Abnormal levels of brain serotonin (5-HT) have been proposed as the cause of OCD. The SH is derived largely from the consistent finding that the group of drugs called *serotonin reuptake inhibitors* (SRIs) help reduce OCD symptoms (see the discussion of depression below). SRIs prevent reuptake of serotonin in the brain, making more available. So it's inferred from their success with OCD patients that OCD must be caused by a *deficiency* of serotonin.

This has been confirmed by brain imaging studies. Also, there are several case reports of symptom improvement when OCD patients use *hallucinogenic drugs* (such as LSD). These drugs are potent stimulators of brain 5-HT. Others have reported a worsening of symptoms after patients take 5-HT antagonist drugs – that is, drugs that *reduce* 5-HT levels (Claridge & Davis, 2003).

An evaluation of the SH

- Although 5-HT is clearly important in understanding the causal mechanisms of OCD, it's not the only neurotransmitter likely to be involved. Excessive *dopamine* may also play a part. For example, haloperidol (a dopamine D2 receptor antagonist) has been used for improving treatment response to SRIs. By blocking D2 receptors, the indirect pathway can better counteract the action of the direct pathway (see Saxena *et al.*'s model above) (Claridge & Davis, 2003).
- Many patients are only partially responsive to SRIs. Almost a third don't respond at all. A range of other 5-HT agonists (which increase 5-HT levels) also fail to improve symptoms – and some even make them

worse. 5-HT depletion studies have typically shown *no* reversal of the symptom improvement induced by SRIs. This reversal is what we'd expect if OCD really is caused by too little 5-HT. Nor does 5-HT depletion have any ill-effects on unmedicated OCD patients (Claridge & Davis, 2003).

- Just because drugs such as SRIs increase 5-HT activity and are effective in alleviating the major symptoms of OCD, it doesn't necessarily follow that the disorder is caused by an excess or depletion of that neurotransmitter. This is like saying that because taking an aspirin gets rid of a headache, headaches are caused by a deficiency of acetylsalicyclic acid (Claridge & Davis, 2003). (This same faulty logic applies, of course, to other disorders: see below.) In fact, more and more sophisticated brain imaging techniques are revealing that OCD symptoms could develop without *any* 5-HT involvement at all (Delgado & Moreno, 1998).

Box 44.5 The major characteristics of PTSD

Increased arousal: severe anxiety, irritability, insomnia, poor concentration. There may also be panic attacks and episodes of aggression.

Persistent defences of avoidance and repression: avoidance of reminders of the events, difficulty in recalling the events at will, detachment, inability to feel emotion ('numbness'), diminished interest in activities.

Intrusions: memories of the traumatic events break through the repression as repeated, intense imagery ('flashbacks'), and distressing dreams. Anxiety increases further during flashbacks and reminders of the event.

There may also be additional maladaptive coping responses, such as excessive use of alcohol and drugs.

(Based on Gelder *et al.*, 1999)

Post-traumatic stress disorder (PTSD)

During the First World War, many soldiers experienced *shell shock* (a shock-like state which followed the traumatic experiences of prolonged combat). In the Second World War, combat fatigue (or 'traumatic neurosis') was used to describe a similar reaction, characterised by terror, agitation or apathy, and insomnia.

Following the Vietnam War, the syndrome was renamed *post-traumatic stress disorder* (PTSD) and first appeared by that name in DSM-III (1980). The term describes an anxiety disorder which occurs in response to an extreme psychological or physical trauma outside the range of normal human experience (Thompson, 1997). Apart from war, such traumas include a physical threat to one's self or family, witnessing other people's deaths, and being involved in natural or human-made disasters. Examples include the Hillsborough football tragedy, the Herald of Free Enterprise cross-channel ferry disaster, and the Paddington rail disaster.

197 people died when the *Herald of Free Enterprise* ferry capsized off Zeebruge, Belgium, in 1987

While Freud considered that at the root of many neurotic disorders is the inability to remember bad experiences (see Chapter 45), the opposite is true in the case of PTSD. As Brewin (1998) says:

> The curse of perpetual reminiscence is a cardinal feature of post-traumatic stress disorder (PTSD), in which sufferers attempt to avoid but cannot prevent vivid, emotionally arousing images repeatedly intruding into their waking or sleeping minds ...

Research has pointed to the fact that intrusive memories are also important in depression. Reynolds & Brewin (1997) compared matched samples of patients with PTSD and depression. While PTSD patients were a little more likely to have intrusive memories (which are also somewhat more vivid and frequent), they're otherwise very similar. Both groups were likely to experience very vivid and highly distressing memories on average several times per week and lasting several minutes (up to an hour). Also for both groups, they're mostly accompanied by physical sensations and a feeling of reliving the event. One of the few differences was that PTSD patients were more likely to report feeling helpless and to have a *dissociative experience,* such as feeling they were leaving their body or seeing themselves as an object in their memory.

PTSD may occur immediately following a traumatic experience or weeks, months and even years later. In the Vietnam War, there were relatively few cases of shell shock or combat fatigue, but on their return to the USA soldiers found it more difficult adjusting to civilian life than did those who fought in the two world wars.

As well as the symptoms described in Box 44.5, Vietnam veterans felt extreme guilt at having survived, while so many of their comrades hadn't. This is also common among survivors of disasters, as are exaggerated startle responses to unexpected stimuli.

Psychological explanations

Unlike other anxiety disorders, the causes of PTSD are largely, if not exclusively, *environmental*. While phobias or OCD tend not to have common background factors, all PTSD sufferers share the experience of having been involved in a profoundly traumatising event.

Sufferers tend to show classically conditioned responses to stimuli present at the time of the event (e.g. Charney *et al.*, 1993). But since not everyone exposed to the traumatic event develops PTSD, other factors must be involved, such as individual differences in people's appraisal of events as stressors (see Chapter 12), and the recovery environment (such as family support and support groups).

The return of memories many years after the traumatic event suggests that keeping busy with socially valued life roles enables a person to avoid processing the traumatic memories. But this prevents the memories from becoming integrated into the individual's worldview. In conditioning terms, thinking about the traumatic event would lead to extinction of the responses associated with it.

Biological explanations

According to Butler (1996), PTSD can be seen as the breakdown of the normal stress response.

ASK YOURSELF...

- Remind yourself how the normal stress response works (see Chapter 12, pages 204–208). Why do you think Butler (1996) describes PTSD as 'too much of a good thing'?

When stress becomes overwhelming, too much adrenaline and noradrenaline produce confusion, and impair learning and memory. Repeated adrenaline rushes seem progressively to sensitise brain chemistry, provoking even greater floods of adrenaline at lower thresholds. For example, one study cited by Butler found that those with childhood histories of physical or sexual abuse were significantly more likely to develop PTSD after combat in Vietnam than those who were without such histories.

Years after the trauma, the nervous systems of PTSD sufferers remain always on alert (as manifested in the startle responses and general emotional reactivity). Butler cites a study of Vietnam veterans who were injected with *yohimbine*, a psychoactive drug from South America that stimulates secretion of noradrenaline. While non-traumatised control participants reported a little heart-pounding, nine of the 15 veterans suffered panic attacks and six had full-blown flashbacks. Yohimbine temporarily disables alpha-2 receptors – brain cell structures which slow the release of adrenaline to the brain. Other research shows that PTSD patients have 40 per cent fewer alpha-2 receptors than normal controls.

The brains of PTSD sufferers release *endorphins* (natural opiates with pain-killing properties: see Chapter 4) far above normal levels, causing a drop in pain sensitivity. This over-activation of a natural anaesthetic response, in the face of something rationally known not to be dangerous (such as watching a movie about Vietnam) may partly explain the numbness reported by some.

Research suggests that moments of overwhelming terror can do lasting damage to the hippocampus (see Chapter 17). Butler (1996) cites three studies using MRI scans which found significant reductions in the size of the hippocampus of traumatised people, including women with histories of prolonged child sexual abuse. Those with the smallest hippocampi displayed the most intense PTSD symptoms, including dissociation (the tendency to 'space out', feel detached from one's body, and have unpredictable lapses of memory). This hippocampal damage may well be caused by an over-*reduction* in cortisol levels (see Chapter 12), which occurs after prolonged stress. Low cortisol levels are associated with brain cell death in the innermost section of the hippocampus (the *dentate gyrus*), thought to contribute to creativity and the recall of long-term memories.

CRITICAL DISCUSSION 44.1 The positive side of PTSD

- Some researchers have described PTSD as continuous with normal adaptive behaviour, rather than a distinctly abnormal reaction (Brewin *et al.*, 1996; Williams & Joseph, 1999). 'Post-traumatic growth' (Tedeschi, 1999; Tedeschi & Calhoun, 1996; Tedeschi *et al.*, 1998) describes positive changes in the areas of perception of self, relationships with others, and philosophy of life.
- The underlying principle is a *changed perspective*. For example, having had sight of death, survivors emerge sadder but wiser. It's this wisdom that prompts survivors to redefine their philosophy of life: it's no longer taken for granted (Joseph *et al.*, 1993), and everyday existence is consequently valued in a new way.
- This is consistent with Seligman & Csikszentmihalyi's (2000) call for the expansion of psychology into a science of *optimal human functioning* – at both the individual and social/community levels. As Linley (2000) puts it:

> From being a discipline with a primarily pathological focus, psychology can expand ... to embrace the pinnacles of human attainment ... psychology can show individuals and their societies how they may flourish, both in the face of and absence of adversity, so that genuine fulfilment might be achieved.

MOOD (AFFECTIVE) DISORDERS

Manic disorder (mania)

Mania is a sense of intense euphoria or elation. A characteristic symptom is a 'flight of ideas': ideas come rushing into the person's mind with little apparent logical connection, and there's a tendency to pun and play with words. Manics have a great deal of energy and rush around, usually achieving little and not putting their energies to good use. They need little sleep and may appear excessively conceited (having 'grandiose ideas' or delusions). They display *disinhibition,* which may take the form of a vastly increased sexual appetite (usually out of keeping with their 'normal' personality), or going on spending sprees and building up large debts.

As we saw in the *Introduction and overview,* mania usually occurs in conjunction with depression (*bipolar disorder*). But in the rare cases in which mania occurs alone, 'bipolar' is also used (*unipolar* refers to episodes of depression alone: see below). Most patients with mania eventually develop a depressive disorder (Gelder *et al.*, 1999).

Strictly, mania on its own, and mixed episodes of both mania and depression are called 'Bipolar 1'. 'Bipolar 2' refers to major depression combined with *hypomania* (less extreme than full-blown mania). 'Manic-depressive' refers to both the unipolar and bipolar forms of affective disorder. Bipolar disorder is much less common than unipolar, occurring in fewer than 10 per 1000, usually before age 50. Each episode lasts about three months (Gelder *et al.*, 1999). Bipolar 1 (mixed episodes) is more common than either Bipolar 1 (mania alone) or Bipolar 2. It affects 1 per cent of the population and usually first appears in the twenties; it occurs equally often in men and women.

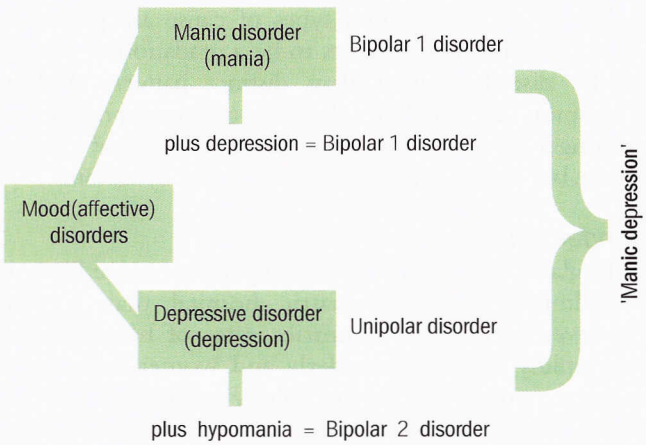

Figure 44.3 The relationship between manic and depressive disorders

Unipolar (depressive) disorder (UDD)

Depression represents the complete reverse of mania. The depressed person experiences a general slowing down and loss of energy and enthusiasm for life. UDD may begin at any time from adolescence onwards, with the average age of onset being the late twenties. With treatment, each episode lasts two to three months, six months or longer if untreated. It affects 20–30 men per 1000, but 40–90 women per 1000 (see Critical Discussion 44.3, page 787). One exception to this general rule is that Jewish men and women are about equally likely to be diagnosed. Jewish men are also more likely to be diagnosed than other male groups (Levav *et al.*, (1997). About 10 per cent of patients eventually commit suicide (Gelder *et al.*, 1999).

CRITICAL DISCUSSION 44.2 The rising tide of suicide

- According to Persaud (in Revill, 2004), the Freudian view is that the act of suicide is a repressed homicide. By hating someone for leaving you, you turn the aggression in on yourself. In killing yourself, of course, you make the other people feel terrible.
- Most of us have suicidal thoughts at some point in our lives. The key factor seems to be how rooted or connected we are to others. Many people will have contemplated suicide, but what stops most of us is our relationships.
- The suicide rate among young British men has tripled since the 1980s, making it the leading cause of death for men aged 19–35. Although numbers fell slightly in 2003, 1300 young men still take their own lives each year in England alone.
- Men tend to use different methods of suicide from women; the former tend to shoot or hang themselves, while the latter usually take an overdose of pills.
- Persaud believes that female disappointment in the modern male (as reflected in the US TV series *Sex and the City*), combined with men's not knowing what to do about it and their inability to admit vulnerability, are part of the explanation for the frightening increase in numbers of male suicides.
- In addition, mental health charities fear that the media are becoming increasingly irresponsible in their treatment of suicide and self-harm (Doward, 2004).

Are there different kinds of depression?

◎ According to Claridge & Davis (2003), mood disorders and anxiety disorders (see below) have much in common:

- they occur much more frequently than other (types of) disorders
- their symptoms are much more continuous with normal personality
- there's considerable symptom overlap between them (such as a focus on negative and threatening events and stimuli); it's even been proposed that there should be a new DSM category, namely

'Mixed Anxiety-Depression' (MAD); many patients with severe psychological impairment don't necessarily meet the full diagnostic criteria for either anxiety or depressive disorder
- according to DSM, 80–90 per cent of depressed patients have symptoms associated with anxiety disorders (such as poor concentration, sleep disturbance, loss of energy, irritability, health worries and panic attacks); conversely, 'depressed mood' is an associated feature of all anxiety disorders
- stress is an important causal factor in both, as well as a consequence of both.

◎ The idea that 'depression' may actually comprise a cluster of loosely connected, distinct disorders has been around since the early 1900s. Claridge and Davis claim that there are at least two quite distinct forms of depression:

- *melancholic type,* characterised by profound *anhedonia* (the inability to find pleasure in life), associated with apathy, inactivity, excessive sleeping and severely depressed mood
- *agitated type,* characterised by difficulty in recovering from emotionally stressful events, and obvious signs of anxiety and restlessness.

Table 44.1 Symptoms of clinical depression (major depressive disorder) (based on Spitzer *et al.*, 1978)

In order to be said to be suffering from clinical depression, a person should have experienced a number of the following symptoms together over a period of time.

A	Persistent low mood (for at least two weeks)	
plus		
B	At least five of the following symptoms:	
	1	Poor appetite or weight loss, or increased appetite or weight gain (change of 1 lb [450 g] a week over several weeks or 10 lb [4.5 kg] in a year when not dieting).
	2	Sleep difficulty, or sleeping too much.
	3	Loss of energy, fatiguability or tiredness.
	4	Body slowed down or agitated (not mere subjective feeling of restlessness or being slowed down, but observable by others).
	5	Loss of interest or pleasure in usual activities, including social contact or sex.
	6	Feelings of self-reproach, excessive or inappropriate guilt.
	7	Complaints or evidence of diminished ability to think or concentrate such as slowed thinking or indecisiveness.
	8	Recurrent thoughts of death or suicide, or any suicidal behaviour.

Winston Churchill (1874–1965), famous British Prime Minister – and depressive

Endogenous vs exogenous depression

A distinction that's deeply embedded within psychiatric thinking is that between *endogenous* ('from the inside') and *reactive* (or 'exogenous', from the outside) depression. The former was intended to denote depression arising from biochemical disturbances in the brain, while the latter was seen as being caused by stressful life experiences. These were also classified as psychotic and neurotic depression respectively, implying that the former is much more serious (see Table 43.4, page 767).

However, the distinction is controversial. According to Gelder *et al.* (1999), both types of cause are present in every case, and there appears to be a gradation of severity of the disorder, rather than distinct patterns. Indeed, Champion (2000) believes that endogenous depression can no longer be defined in terms of the absence of external causes, but by the presence of more severe symptoms.

Gender differences

In England, a woman is about 40 per cent more likely to be admitted to a psychiatric hospital than a man. However, as in other countries, rates of hospitalisation rise rapidly among the elderly and women outnumber men by two to one in the elderly population (75 and over). When admission rates for other categories of disorder are taken into account (such as the very similar rates between males and females for schizophrenia), it's depression that contributes most to the high overall rate of treated mental illness among women (Cochrane, 1995). While there are no sex differences in the rate of bipolar disorder (Strickland, 1992), women are two to three times more likely to be diagnosed with unipolar disorder than men (Williams & Hargreaves, 1995).

CRITICAL DISCUSSION 44.3 Are women naturally disposed towards depression?

- A popular and widely held view is that women are naturally more emotional than men, and so are more vulnerable to emotional upsets. Hormonal fluctuations associated with the menstrual cycle, childbirth, the menopause and oral contraceptives have all been proposed as the mechanism which might account for the sex difference (Cochrane, 1995).
- Cochrane believes that there's no evidence that biochemical or physiological changes involved in the menopause, for example, have any direct effect on psychological functioning. But while the hormonal changes of the menstrual cycle may not be sufficient on their own to cause clinical depression, they may tend to reactivate memories and feelings from a previous period of major depression (caused by other factors) (Williams & Hargreaves, 1995).
- According to the UK Department of Health, the months surrounding childbirth carry the greatest risk for women of developing mental illness. The most common is *mood disorder with postpartum onset or postnatal depression* (PND), affecting 10–15 per cent of all new mothers (Hill & Revill, 2004).
- However, some believe that mothers are being overdiagnosed with PND by a medical industry intent on pathologising childbirth. The 'baby blues' affects about 90 per cent of new mothers and is associated with hormonal changes, exhaustion after the birth and rapid readjustment to a different way of life. PND, however, is a far more serious condition and can make it very difficult for the mother to bond with her child (Hill & Revill, 2004).
- Hormonal changes cannot explain why the discrepancy in the female/male rates of depression is so large or why only some women are affected. Cochrane (1995) identifies several *non-biological explanations* of women's greater susceptibility to depression:
  - girls are very much more likely to be abused, particularly sexually, than boys, and victims of abuse are at least twice as likely to suffer clinical depression in adulthood as non-victims. Abuse alone could account for the female–male difference in depression rates
  - a woman's acceptance of the traditional female gender role involves accepting that she'll have relatively little control over her life. This may contribute to *learned helplessness* (see below)
  - the female–male difference in the rate of depression is at its greatest between the ages of 20 and 50, during which time marriage, childbearing, motherhood, and the 'empty nest' syndrome will be experienced by a majority of women
  - Cochrane (1983) argues that depression may be seen as a *coping strategy* that's available to women, in contrast to those of men (including alcohol and drugs, and their work). Not only is it more acceptable for women to admit to psychological symptoms, but these may represent a means of changing an intolerable situation. But Callaghan & O'Carroll (1993) warn that:

    Unhappiness about their domestic, social, and political circumstances lies at the root of many women's concerns. This unhappiness must not be medicalised and regarded as a 'female malady' ...

Explanations of depression

In addition to the causal factors discussed in Critical Discussion 44.3, all the major theoretical approaches have attempted to explain depression. Probably the most influential of these – both currently and in recent years – has been the cognitive model, especially Beck's (1963) *cognitive triad of depression*. Because his form of cognitive–behaviour therapy (CBT) is mainly intended to treat depression, this – and other cognitive explanations – will be discussed in Chapter 45.

The role of genetic factors

- *First degree relatives* (parents, siblings and children) of severely depressed patients have a higher risk of affective disorders (10–15 per cent) than the general population (1–2 per cent). This increased risk is even higher among relatives of patients with early onset. But, curiously, among first degree relatives of patients with bipolar disorder there are more cases of UDD than bipolar disorder (Davison & Neale, 2001).
- Concordance for bipolar disorder (about 70 per cent) is the same among MZs reared together or apart. This compares with 23 per cent for DZs.
- Adoption studies confirm the importance of genetic factors. The natural parents of adoptees with a bipolar disorder have a higher rate of affective disorder than do natural parents of adoptees without bipolar disorder (Gelder *et al.*, 1999).
- Genetic factors in UDD seem to be less decisive than in bipolar disorder. Also, there's some evidence that genetic factors are more important in women than in men (Davison & Neale, 2001: but see Critical Discussion 44.3).

Neurochemical explanations

According to the *monoamine hypothesis* (MAOH), a depletion of serotonin, noradrenaline and/or dopamine underlies the melancholic symptoms of depression. High levels induce mania. Serotonin (5-HT), norepinephrine (noradrenaline) and dopamine are collectively known as *monoamine oxidase* (MAO) *transmitters*. By far the greatest number of studies on these have involved 5-HT (Claridge & Davis, 2003).

The supporting evidence is based largely on working backwards from what's known about the mechanisms of drugs that either induce or reduce depressive symptoms.

It was discovered in the mid-1950s that depression was a common side-effect of one of the first effective drugs for treating high blood pressure (reserpine). It was known that reserpine reduced the levels of brain 5-HIAA (a chemical produced when 5-HT is broken down). Also in the 1950s, tricyclics and monoamine oxidase inhibitors (MAOIs) were found to be effective in relieving depression (see Chapter 45):

- *tricyclics* prevent some of the reuptake of both noradrenaline and serotonin; this leaves more of the transmitter in the synaptic gap, making transmission of the next nerve impulse easier (see Chapter 4)
- the newest antidepressants are called *serotonin reuptake inhibitors* (SRIs), because they act more selectively on serotonin (this is why they're sometimes called SSRIs – *specific serotonin reuptake inhibitors*). They raise levels of serotonin (5-HT) and have a well-established antidepressant effect; examples are fluoxetine (most familiarly marketed as Prozac). Because SSRIs are effective in treating UDD, a stronger link has been established between low levels of 5-HT and depression (Davison & Neale, 2001; Gelder *et al.*, 1999)
- MAOIs prevent the enzyme monoamine oxidase (MAO) from breaking down the neurotransmitters; this increases the levels of both 5-HT and noradrenaline in the brain. Like the tricyclics, this compensates for the abnormally low levels of these neurotransmitters in depressed people.

An evaluation of the MAOH

- The MAOH is the longest-standing and most persistent biological theory of depression (Claridge & Davis, 2003).
- It's known that all the main antidepressants have an immediate effect on the levels of 5-HT and noradrenaline in the brain. But it sometimes takes up to 7–14 days for them to have any noticeable effect on patients' symptoms. It seems that by the time the drugs begin to 'work', the neurotransmitter levels have returned to their previous state. So a simple increase in neurotransmitter levels isn't a sufficient explanation for why the drugs alleviate depression (Davison & Neale, 2001).
- An *indirect* way of testing the role of 5-HT is to measure concentrations of a particular *metabolite*. This is a by-product of the breakdown of the neurotransmitters, found in urine, blood serum and cerebro-spinal fluid (CSF). These are found to be lower in patients with depression, especially in those who commit violent suicide (Claridge & Davis, 2003). This could, however, be the result of many different kinds of biochemical abnormality. Also, the lower concentrations probably aren't a direct indication of levels of either 5-HT or noradrenaline *in the brain*. Metabolites measured this way could reflect neurotransmitters anywhere in the body (Davison & Neale, 2001).
- A more *direct* test comes from experimental depletion studies involving normal participants. When they're given drugs that *reduce* levels of 5-HT and noradrenaline in the brain, these people *don't* usually experience depressive symptoms (Claridge & Davis, 2003). Nor do the symptoms of unmedicated depressed patients become worse (Delgado, 2000).

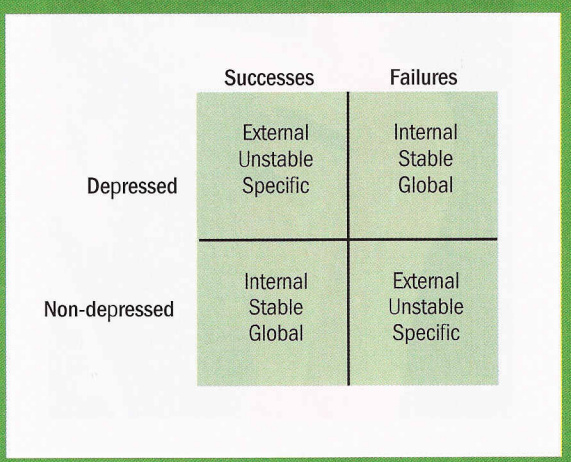
Box 44.6 Other risk factors for depression

- Tebartz *et al.* (2000) found that depressed people have an enlarged amygdala (which is known to play a role in emotional information processing: see Chapter 4). The amygdalae of female patients were significantly larger than those of males.
- Chronically (naturally occurring) low levels of cholesterol are associated with depressive symptoms and suicide, even when age, energy intake, alcohol consumption and the presence of chronic disease are controlled (Steegmans *et al.*, 2000).

Learned helplessness theory (LHT)

Strictly, learned helplessness is the original of three related cognitive theories of depression. The basic premise of *learned helplessness theory* (LHT) is that depression in humans is a form of *learned* helplessness (LH) (Seligman, 1974). This is based on Seligman's experiments with dogs (see Key Study 11.4, page 182). On the basis of these observations, Seligman proposed that animals acquire a sense of helplessness when confronted with uncontrollable aversive stimulation. Later, this sense of helplessness impairs their performance in stressful situations that *can* be controlled. They seem to lose the ability and motivation to respond effectively to painful stimulation.

By extension, LH could provide an explanation for at least certain forms of depression in humans. Seligman believed that, like his dogs, many depressed people appear passive in the face of stress. They fail to initiate actions that might allow them to cope. Also, like depressed people, Seligman's dogs lost their appetite and lost weight. They also showed reduced levels of noradrenaline.



By 1978, research with humans began to reveal several inadequacies of LHT. For example, many depressed people blame themselves for their failures, but this is incompatible with the claim that they see themselves as helpless. Also, the experience of being unable to control the outcome of one particular situation (helplessness) doesn't necessarily lead to clinical depression in most people. These and other findings suggest very strongly that LH cannot tell the whole story. LHT was revised by Abramson, Seligman and Teasdale in 1978. The major change they proposed was in terms of *attribution theory principles.*

ASK YOURSELF...

- How do you think this modified LHT might have tried to explain depression? (See Chapter 23.)

Box 44.7 The attributional theory of depression (Abramson *et al.*, 1978)

- When we experience failure, for example, we try to explain it (just as we try to account for our successes); this is perfectly 'normal'. What's associated with depression is a particular *pattern* of attributions (or *attributional style*) – that is, a tendency to make particular kinds of *causal inferences*, rather than others.
- The 'depressed attributional style' (DAS) is based on three key dimensions, namely *locus* (whether the cause is internal or external, to do with the actor him/herself or some aspect of the situation), *stability* (whether the cause is stable or unstable, a permanent feature of the actor or something transient), and *global* or *specific* (whether the cause relates to the 'whole' person or just some particular feature or characteristic). The depressed person believes that his/her failure:
  - (a) is caused by *internal* factors ('I'm stupid')
  - (b) reflects *stable*, long-term, relatively permanent factors ('I never do well on tests or exams')
  - (c) reflects a *global*, pervasive deficiency – that is, failure applies to all or most aspects of his/her life ('I get everything wrong').

Attributional styles for success and failure in depressed people (based on Abramson *et al.*, 1978; Abramson & Martin, 1981)

- People diagnosed as clinically depressed are more likely to show this pattern when given, for example, the *Attributional Style Questionnaire* (ASQ) (Seligman *et al.*, 1979).
- Equally important, the person who's *prone* to becoming depressed may also display the DAS. It's believed to play a mediating role between negative life events and adverse physical and mental health outcomes. When such depression-prone people experience stressors, they're more likely to develop the symptoms of depression, and their self-esteem is shattered (Peterson & Seligman, 1984).

An evaluation of the attributional theory

- This clearly is an improvement on LHT, because it adds in cognitive factors that are missing from the latter. There's a vast amount of research into attribution within social psychology, so Abramson *et al.* are drawing on a well-established research area to supplement the idea of helplessness. The concept of attributional style represents a *diathesis*, a predisposition to develop a particular mental disorder under stressful conditions (see the discussion of schizophrenia below, page 798).
- Seligman *et al.* (1979) gave their ASQ to college students. As predicted by the theory, mildly depressed students more often attributed their failures to personal (internal), global and stable inadequacies than did non-depressed students.
- A problem faced by most cognitive explanations of psychopathology is accounting for where the DAS comes from in the first place. It's thought to stem from childhood experiences, but there's little empirical support for this claim. However, Rose *et al.* (1994) found that DAS is related to sexual abuse in childhood, as well as to parental overprotectiveness, harsh discipline and perfectionistic standards.
- *Hopelessness theory* (HT) (Abramson *et al.*, 1989) is the latest version of the theory. According to HT, some forms of depression (hopelessness depression) are caused by a state of hopelessness, an expectation that desirable outcomes won't occur, or that undesirable ones will occur and that there's nothing the person can do to prevent them (that is, helplessness). HT proposes that there may be other diatheses in addition to DAS. One of these is low self-esteem and a tendency to infer that negative life events will have serious negative consequences.

An overall evaluation of helplessness/hopelessness theories

Davison & Neale (2001) and Davison *et al.* (2004) point out some general problems with all three helplessness-related theories.

- Seligman (1974) was originally trying to explain the similarity between LH and what used to be called *reactive depression* (see above, page 786). Abramson *et al.* (1989) talk about a hopelessness depression, which refers both to the presumed cause of the depression and to a set of symptoms that don't quite match the DSM criteria.
- Some research has been conducted with clinical populations (people actually diagnosed as having a depressive disorder) (such as Abramson *et al.*, 1978). But many studies have involved college students selected on the basis of the Beck Depression Inventory (BDI), or have simply tried to predict increases in BDI scores. But the BDI wasn't designed

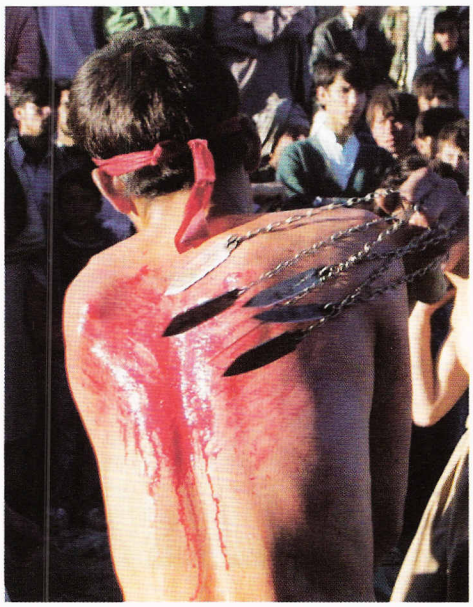
to diagnose depression, only to assess its severity among those already diagnosed. People selected on the basis of raised BDI scores aren't comparable to those with clinical depression. For example, high scorers have been found to score much lower when retested two to three weeks later. Also, the finding that the ASQ can predict BDI scores doesn't necessarily mean that it can predict the onset of actual clinical depression.

- We've already noted the *comorbidity* of depression and anxiety. We need to be sure that the theories are truly about depression, rather than about negative affect in general. DAS seems to be related to anxiety and general distress, as well as depression.
- A key assumption is that the DAS is a persistent part of the make-up of the depressed person. As a diathesis, it must be 'in place' before the person experiences some stressor. But Hamilton & Abramson (1983) showed that it disappears following a depressive episode.

Despite these problems, Davison & Neale (2001) and Davison *et al.* (2004) conclude that these theories have clearly stimulated a great deal of research and theorising about depression. This is likely to continue for many years to come.

Culture and depression

While there are an estimated 340 million people worldwide affected by depressive disorders (making it the most common of all mental disorders: Lyddy, 2000), Price & Crapo (1999) point out that various researchers have denied the presence of native concepts of depression among groups as diverse as the Nigerians, Chinese, Canadian Inuit, Japanese, Malaysians, and the Hopi Native Americans. Price and Crapo ask:



If depression, as currently defined in Western culture and psychiatric diagnosis, is not found in non-Western cultures, how do we know that 'depression' is not merely a Western folk concept, analogous to other culture-specific conditions such as koro, kayak-angst, amok or susto?

CRITICAL DISCUSSION 44.4 The social construction of happiness and sadness

- According to Moghaddam (2002):

  ... depression, as it is medically recognized and treated in Western societies, is fundamentally a social construction. This is not to say that people in other historical eras and in other societies have not experienced the same biological processes as do depressed people in Western societies today, but that the meanings and implications of experiences arising from such processes have been different in major ways ...

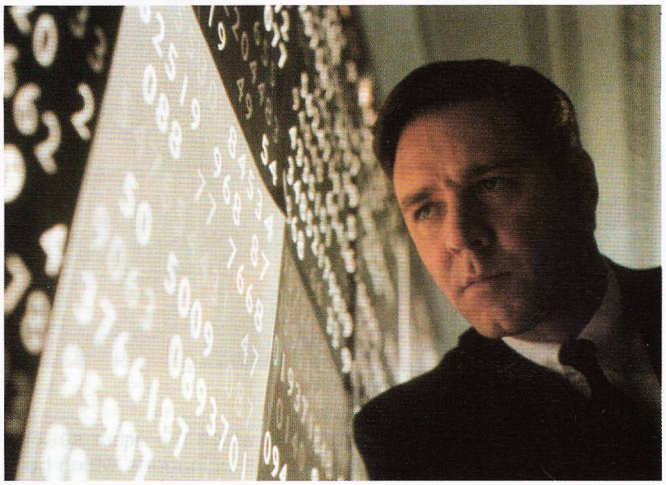
- For example, in modern western societies, especially the USA, greater and greater emphasis is being placed on presenting the self in a positive, happy way ('I'm doin' great'). But while this might be normative in the USA, it wouldn't be in most eastern cultures, and someone displaying such a style would be regarded negatively.
- Conversely, even in western culture, 'negative' emotions (sadness, melancholy, depression) haven't always been shunned. They're a normal part of life and should be valued as an essential feature of human experience. The 'cult of melancholy' during the mid-eighteenth to late nineteenth centuries was reflected in poetry and is still prominent in Farsi-speaking countries. For example, among Shiite Muslims (the religion of over 96 per cent of Iranians and 45 per cent of Iraqis) several important religious ceremonies involve participants weeping and wailing, self-flagellation, and expressing – and experiencing – misery.

A flagellating Shi'ite Muslim

- The feelings of guilt and self-blame, loneliness and anxiety, commonly reported by depressed people in western societies (see above) don't seem to be part of people's experience in non-western societies. The latter typically look outside themselves, and refer to the rain, seasons, fate and various other external phenomena to explain their experiences (Moghaddam, 2002).

According to Kaiser *et al.* (1998), DSM-IV recognises the vital role of culture in the expression and diagnosis of disorders (see Chapter 43). It encourages clinicians to keep cultural considerations in mind when assessing patients on each of the five axes. In the section dealing with depression, conditions which appear most often in specific cultures are outlined, as well as cultural variations in the manifestation of symptoms. For example, in some

cultures people tend to present with somatic complaints (such as aches and pains), while in others affective symptoms are more common (such as sadness). The task of the clinician is to take the norms of the individual patient's cultural reference group into account, while at the same time avoiding cultural stereotypes (Kaiser *et al.*, 1998).



ASK YOURSELF...

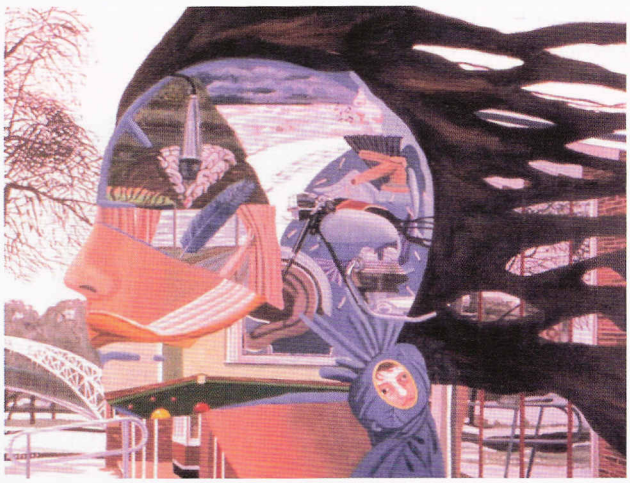
- How does this discussion of cultural aspects of depression relate to the discussion in Chapter 43 of whether schizophrenia is culture-free? (See Critical Discussion 43.3, page 768.)

SCHIZOPHRENIA

As we noted in the *Introduction and overview,* what we now call schizophrenia was originally called *dementia praecox* ('senility of youth') by Kraepelin (1896). Kraepelin believed that the typical symptoms (namely, delusions, hallucinations, attention deficits, and bizarre motor activity) were due to a form of mental deterioration which began in adolescence. But Bleuler (1911) observed that many patients displaying these symptoms didn't go on deteriorating, and that illness often began much later than adolescence. Consequently, he introduced the term 'schizophrenia' instead (literally 'split mind' or 'divided self') to describe an illness in which 'the personality loses its unity'.

According to Clare (1976), the diagnosis of schizophrenia in the UK relies greatly on Schneider's (1959) *first-rank symptoms* (FRSs).

Russell Crowe as John Forbes Nash, mathematical genius who develops schizophrenia, in *A Beautiful Mind* (2001)



Schneider's FRSs are *subjective experiences,* which can only be inferred on the basis of the patient's verbal report. Slater & Roth (1969) regard hallucinations as the least important of all the major symptoms, because they aren't exclusive to schizophrenia (this is also true of delusions: see below). Slater & Roth identify four additional symptoms, which are *directly observable* from the patient's behaviour.

Table 44.2 Schneider's (1959) first-rank symptoms of schizophrenia

Passivity experiences and thought disturbances: *thought insertion* (thoughts are inserted into one's mind from outside and are under external influence), *thought withdrawal* (thoughts are removed from one's mind and are externally controlled), and *thought broadcasting* (thoughts are broadcast to/otherwise made known to others). External forces may include the Martians, the Communists and the Government.
Auditory hallucinations (in the third person): *hallucinatory voices* are heard discussing one's thoughts or behaviour as they occur (a kind of running commentary), arguing about oneself (or using one's name), or repeating one's thoughts out loud/anticipating one's thoughts. They're often accusatory, obscene and derogatory, and may order the patient to commit extreme acts of violence. They're experienced as alien or under the influence of some external source, and also in the light of concurrent delusions (e.g. the voice of God or the devil: see below). The hallucinations of patients with *organic* psychoses are predominantly visual.
Primary delusions: *false beliefs* (incompatible with reality, usually of *persecution* or *grandeur*) held with extraordinary conviction, impervious to other experiences or compelling counter argument/contradictory evidence. The patient may be so convinced of their truth that they act on the strength of their belief, even if this involves murder and rape (as in the case of Peter Sutcliffe, the 'Yorkshire Ripper').

Table 44.3 Major symptoms of schizophrenia (based on Slater & Roth, 1969)

Thought process disorder: the inability to keep to the point, being easily distracted/side-tracked. In *clang associations* (e.g. 'big', 'pig', 'twig'), words are 'thrown together' based on their sound rather than their meaning; this produces an apparently incoherent jumble of words ('*word salad*'). Also the inability to finish a sentence, sometimes stopping in the middle of a word (*thought blocking*), inventing new words (*neologisms*) and interpreting language (e.g. proverbs) literally.
Disturbance of affect: events/situations don't elicit their usual emotional response (*blunting*), there's a more pervasive, generalised absence of emotional expression (as in minimal inflection in speech, and lack of normal variation in facial/bodily movements used to convey feelings: *flattening of affect*), loss of appropriate emotional responses (e.g. laughing/getting angry for no apparent reason, changing mood very suddenly, giggling when given some bad news: *incongruity of affect*).
Psychomotor disorders: muscles in a state of semi-rigidity (*catalepsy*), grimacing of facial muscles, limb twitching, stereotyped behaviours (such as constant pacing up and down), or assuming a fixed position for long periods of time, even several years in extreme cases (*catatonic stupor*).
Lack of volition: inability to make decisions or carry out a particular action, loss of will power or drive, loss of interest in what's going on and affection for friends/family.

Broah Schizophrene by Brian Charnley.
This is one of a number of pictures in which the artist set out to depict some of the delusions and hallucinations which he himself was experiencing while suffering from schizophrenia. These included the feeling that other people had access to all his thoughts

So who's right – Schneider or Slater and Roth?

According to Claridge & Davis (2003), 'first-rank symptoms' imply that:

> ... certain experiences of people clinically labelled 'schizophrenic' are so bizarre, incomprehensible, and distant from the normal that we are surely convinced that these must be central to the disorder.

In other words, FRSs seem to describe the 'fundamental', core features of schizophrenia. But like Slater and Roth, Bleuler regarded hallucinations and delusions as *accessory* (secondary) symptoms – that is, they're psychological consequences of a more primary, physical process that constitutes the real core. Claridge and Davis believe that the DSM and ICD criteria for diagnosing schizophrenia are a confused mix of these views – although there's a bias towards FRSs. They consider this bias to be understandable, since:

> ... Reporting that aliens in outer space are responsible for the thoughts in your head certainly seems more crazy than bemusing your neighbours with your stream of consciousness style of conversation!

But, unlike most diagnostic categories, there's *no essential* symptom that must be present for a diagnosis of schizophrenia to be made (Davison & Neale, 2001).

Positive and negative symptoms

Most of Schneider's FRSs are what are known as *positive symptoms* (or Type I) – that is, excesses or distortions, the *presence of active symptamatology*. They're what define, for the most part, an *acute* episode, and are occurrences beyond normal experience (Javitt & Coyle, 2004). Typically, patients have several acute episodes, between which are less severe but still very debilitating symptoms.

Most of Slater and Roth's symptoms are *negative* (Type II) symptoms. They consist of behavioural deficits, *lack of* or *poverty of* behaviour. These symptoms tend to endure beyond the acute episodes, and have a profound effect on patients' lives. The presence of several negative symptoms is a strong predictor of a poor quality of life two years after leaving hospital (Davison *et al.*, 2004).

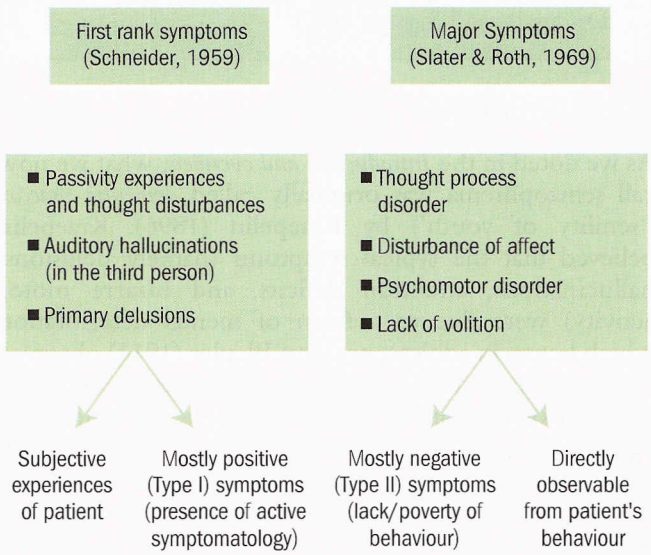


Figure 44.5 Summary of different attempts to define the major characteristics of schizophrenia

A third group of symptoms (*disorganised* or *cognitive*) refer to difficulty in maintaining a logical, coherent flow of information, maintaining attention and thinking on an abstract level, and bizarre behaviour (Davison *et al.*, 2004; Javitt & Coyle, 2004).

The distinction between positive and negative symptoms is very important in relation to research into the *causes* of schizophrenia (see below). According to Claridge & Davis (2003), currently the most widely quoted research classification is based on this distinction. But despite its popularity, they believe there are several problems with the distinction.

- Subjective accounts of psychotic experience suggest that it's doubtful whether negative symptoms define a *type* of schizophrenia. It's more likely that positive and negative symptoms represent alternating *states* occurring at different times within the same individual.
- If it *does* define a 'type' of schizophrenia, the negative form probably refers to the chronic end-state. Some patients progress into this after years of adaptation to their more acute ('florid') episodes.
- If a diagnosis of schizophrenia is based on an initial episode that consists solely of negative symptoms, it won't be very convincing. For example, how do

negative symptoms differ from those of depression (see above)? Also, flat affect can be a side-effect of antipsychotic medication (Davison *et al.*, 2004). For all these reasons, 'negative symptom' is ambiguous.

◎ Despite these criticisms, the positive/negative distinction (or some elaboration of it) is probably along the right lines as a rough template of how schizophrenic symptoms can vary. It's easily recognisable to psychiatrists and psychologists.

Varieties of schizophrenia

DSM-IV-TR distinguishes three types of schizophrenia (as initially proposed by Kraepelin). These are *disorganised, catatonic* and *paranoid*. These are described in Table 44.4.

Other types that have been identified include *simple* and *undifferentiated*.

Simple schizophrenia

This often appears during late adolescence and has a slow, gradual onset. The main symptoms are gradual social withdrawal and difficulty in making friends, aimlessness and idleness, blunting of affect, loss of volition and drive, and a decline in academic or occupational performance. Such people may become drifters or tramps, and are often regarded by others as idle and 'layabouts'. There are no major psychotic symptoms as in the other types. Only ICD actually distinguishes this type, which is still used in some countries.

Undifferentiated (atypical)

This category is meant to accommodate patients who cannot easily be placed elsewhere – that is, psychotic conditions that meet the general diagnostic criteria for schizophrenia, but that don't conform to any of the subtypes (due to either insufficient or overlapping

Robin Williams (left) in a scene from *Awakenings*. Patients with sleeping sickness (as portrayed in the film) have often been misdiagnosed with catatonic schizophrenia

Table 44.4 The three types of schizophrenia as identified by DSM-IV-TR

Disorganised schizophrenia

- This is probably the nearest thing to many people's idea about what a 'mad' or 'crazy' person is like (see text above). It's what Kraepelin called hebephrenic.
- It's normally diagnosed only in adolescents and young adults.
- Mood is shallow and inappropriate. Thought is disorganised, and speech is incoherent. This makes it difficult for the listener to follow. Delusions and hallucinations are fleeting and fragmentary, and behaviour is irresponsible, unpredictable, silly or mischievous, childish or bizarre. The person may sometimes become violent (if, for example, s/he's approached while hallucinating).
- The person may become incontinent, and tends to ignore personal appearance and hygiene.

Catatonic schizophrenia

- The patient may alternate between extremes such as (a) hyperkinesis (hyperactivity) and stupor (a marked reduction of spontaneous movements and activity), or (b) automatic obedience ('command automatism') and negativism (apparently motiveless resistance to all instructions/attempts to be moved or doing the opposite of what's asked).
- There may be episodes of apparently purposeless motor activity combined with a dreamlike (oneroid) state with vivid scenic hallucinations.
- Other characteristics are mutism, posturing (the voluntary assumption of inappropriate and bizarre postures) and waxy flexibility (maintenance of the limbs and body in externally imposed positions).
- Onset may be more sudden than with other types of schizophrenia, but the patient is likely to have shown previous apathy and withdrawal from reality.

Paranoid schizophrenia

- This is dominated by relatively stable, often paranoid delusions (although delusions of grandeur are also quite common). These may be accompanied by vivid auditory hallucinations.
- Also common are ideas of reference. The patient incorporates unimportant events within a delusional framework, and reads personal significance into other people's trivial actions. For example, they might think that overheard fragments of a conversation, or something on TV or in a magazine, are about them.
- Paranoid schizophrenics also tend to be agitated, argumentative, angry and sometimes violent, but in other respects, they're less disturbed (the personality is better preserved) than in the other kinds. The person remains emotionally responsive, and s/he is more alert and verbal than other types. Although their language is filled with references to delusions, it isn't disorganised.
- It's the most homogeneous type – that is, paranoid schizophrenics are more alike than those in other categories.

(Based on Gelder *et al.*, 1999; Davison and Neale, 2001)

symptoms). '*Residual*' is used when the patient no longer meets the full criteria, but still shows some signs of illness. This is a 'supplementary' type used in DSM.

Are the sub-types really different?

With the possible exception of paranoid schizophrenia, psychiatrists find it very difficult to tell these 'sub-types' apart. Some patients present symptoms of one sub-group at one time, then those of another sub-group later (Gelder *et al.*, 1999). Assigning someone to a particular sub-type provides very little information that helps either in treatment or predicting the outcome of the illness (poor predictive validity: Davison & Neale, 2001).

Also, catatonic symptoms are much less common now than they were 50 years ago. This could be because drug therapy works effectively on bizarre motor processes. Alternatively, the apparently high prevalence of catatonic schizophrenia during the early twentieth century may have been due to misdiagnosis (Boyle, 1991). There are similarities between it and *encephalitis lethargica* (sleeping sickness). Many cases of the latter may have been diagnosed as catatonic schizophrenia. This was portrayed in the film *Awakenings* (based on the book by Oliver Sacks).

Theories of schizophrenia

Box 44.8 Some general considerations regarding research problems and strategies (based on Claridge & Davis, 2003)

- Schizophrenia is *heterogeneous* (there are many different symptoms that can be involved, and different sub-types are officially recognised: but see above). This makes it almost certain that attempts to give a *single* explanation will fail.
- Patients don't just differ from each other (*between-subject differences*). The same patient can show considerable variation on different occasions (*within-subject differences*). For example, individual schizophrenics show enormous day-to-day fluctuations in simple physical responses (such as galvanic skin response/GSR). But most studies take only a *single* measure. This may be a particular problem in the case of schizophrenia, because what causes this individual instability of function may itself be an important clue to the nature of the disorder.
- People with acute symptoms may be distracted by delusional thoughts about the experimenter. Or they may just not be looking at the computer screen that test stimuli are presented on. A partial solution to this problem is to test people who are taking antipsychotic medication. But then we cannot be sure whether their performance reflects a genuine feature of the illness or an effect of the drugs!
- This makes the study of *schizoid* and *schizotypal personality disorder* (SPD or *schizotypy*) very important. The symptoms of schizophrenia can sometimes appear in a rather muted (toned-down) form. This gave rise to the idea of the *schizophrenic spectrum* (a range of schizophrenia-like disorders). SPD has received the most attention as a possible mild variant of schizophrenia. Diagnostic criteria for SPD include ideas of reference, odd beliefs or magical thinking, unusual perceptual experiences, odd thinking and speech, suspiciousness, inappropriate affect, odd eccentric behaviour or appearance, a lack of close friends and excessive social anxiety.

  If people high on schizotypy share important characteristics with schizophrenics, then by studying the former it becomes possible to study 'schizophrenia' without the confounding effects of acute mental disturbance or medication. This 'schizotypy strategy' is used to examine possible *mechanisms* involved in psychotic disorder. This includes the *genetics* of schizophrenia (see text below).

Is schizophrenia a brain disease?

Not only is schizophrenia one of the most serious forms of mental disorder but, as we saw in Chapter 43, it has become the focus for the whole controversy surrounding the medical model. Remember, Szasz distinguishes between neurological disorders and problems in living, leaving no room for 'mental illness'. So, is there evidence to suggest that schizophrenia is a neurological disorder?

When Kraepelin first identified *dementia praecox*, he was convinced that it was a physical disease like any other. The neuropathological changes associated with *general paralysis of the insane* (caused by syphilis) and *Alzheimer's disease* had just been discovered, and he expected that similar 'markers' would be found for schizophrenia and manic-depressive illness.

However, schizophrenia was categorised as a *functional psychosis* up until 1978 when, according to Gershon & Rieder (1992), the then new CT scan (see Chapter 4) was used for the first time to study the brains of chronic schizophrenics (by Johnstone *et al.* at the Clinical Research Centre in Middlesex, England). It revealed that chronic schizophrenics show an increase in the size of the lateral cerebral ventricles (the fluid-filled spaces in the middle of the brain), and other X-ray evidence confirmed that there was less brain tissue (especially in the medial temporal lobe). This was subsequently confirmed by MRI scans which, along with postmortem examinations, also revealed that schizophrenics have smaller hippocampi and part of their limbic system is also smaller. Gershon and Rieder also cite research which has shown reduced blood flow in the frontal cortex of schizophrenics, implying decreased neuronal activity. Postmortems also show that certain groups of neurons are organised in an abnormal way, or are connected differently, compared with non-schizophrenics.

An evaluation of the neurological disorder explanation

- All these differences are found when patients first develop symptoms (and may even precede the onset of symptoms), which suggests that they're not the result of being ill for a long time or of medication (Harrison, 1995). Also, they don't progress over time, nor is there any evidence of neural scar tissue (*gliosis*) that's normally found in degenerative disorders (such as Alzheimer's and Huntington's). This suggests a *neurodevelopmental* disorder, that is, a failure of brain tissue to develop normally, such as failure of neuronal growth or neuronal connections, or a disturbance in the 'pruning' of neurons that normally takes place between three and 15 years of age (Gershon & Rieder, 1992: see Chapters 4 and 37).
- However, the differences are apparent only if a group of schizophrenics is compared with a group of non-schizophrenics: no-one can yet diagnose schizophrenia in an individual based solely on a brain scan or looking down a microscope (Harrison, 1995). Even if this could be done, the more fundamental question as to why some people develop these disorders and others don't would remain unanswered. The cognitive and affective abnormalities involved in psychosis are so severe that it's reasonable to expect brain abnormalities to be involved (Frith & Cahill, 1995), but the data are largely *correlational*.

ASK YOURSELF...

- How do psychologists interested in individual differences try to separate the effects of variables (potential causes of those differences) that are correlated?
- How could these methods be applied here? (See Chapter 41.)

- Individual studies have regularly shown differences between schizophrenics and control samples. But replicable effects *across* studies have remained elusive (Claridge & Davis, 2003). For example, a review by Chua & McKenna (1995) concluded that there was no reliable evidence for gross structural or functional cerebral abnormality that could be said to characterise schizophrenia as a diagnostic category. The only exception was lateral ventricular enlargement; but the degree of enlargement is modest, many patients don't show any enlargement at all, and enlarged ventricles are found in other disorders (such as mania) (Davison & Neale, 2001). Also, enlarged ventricles are more of a vulnerability factor than an immediate cause of the disorder.
- It's more likely that different brain circuits underlie different clusters of symptoms. For example, people with known abnormalities in their temporal lobe often show schizophrenia-like symptoms. Neuroimaging studies involving schizophrenic patients support this link, and suggest that it's specifically *positive* symptoms that are associated with this dysfunction (Bogerts, 1997). *Negative* symptoms may be related to the *frontal* lobe. Schizophrenics show 'hypofrontality'. This is seen as either (a) reduced activity relative to other brain regions, or (b) failure of the prefrontal cortex (PFC) and associated structures to be appropriately activated by cognitive tasks (Velakoulis & Pantelis, 1996). Performance deficits on neuropsychological tests of frontal lobe function are much greater in those rated high on negative symptoms (Mattson *et al.*, 1997). This suggests that their core cognitive failure is *indirect,* due to *motivational* effects (see Table 44.3).

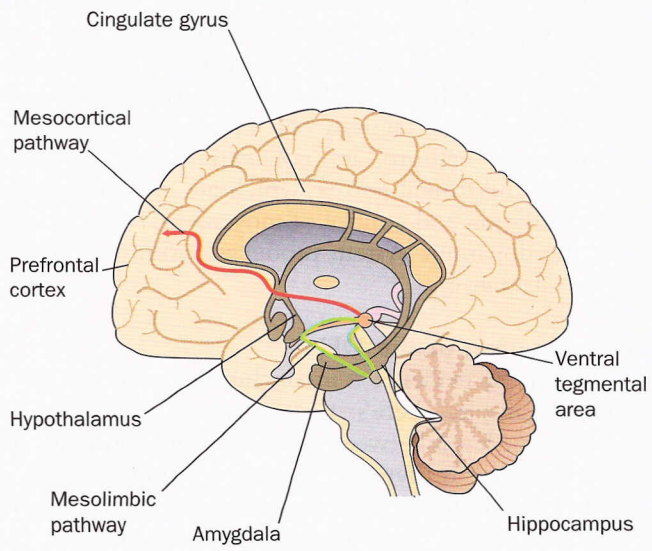
The biochemical theory of schizophrenia

According to the *dopamine hypothesis* (DH), the direct cause of schizophrenic symptoms is an *excess* of the neurotransmitter dopamine. The evidence for this hypothesis comes from three main sources:

- postmortems on schizophrenics show unusually high levels of dopamine, especially in the limbic system (Iversen, 1979)
- anti-schizophrenic drugs (such as chlorpromazine) are thought to work by binding to dopamine receptor sites, that is, they inhibit the ability of the dopamine (D2) receptors to respond to dopamine, thus reducing dopamine activity (see Chapter 45). These drugs produce side-effects similar to the symptoms of Parkinson's disease, which is known to be caused by low levels of dopamine in particular nerve tracts
- high doses of L-dopa (used in the treatment of Parkinson's disease) can sometimes produce symptoms very similar to the psychomotor disorders seen in certain types of schizophrenia. High doses of amphetamines induce *amphetamine psychosis* (AP), which closely resembles paranoid schizophrenia and can exacerbate the symptoms of a patient with schizophrenia (see Chapter 8). Both these drugs are believed to increase the activity of dopamine; dopamine-containing neurons are concentrated in the basal ganglia and frontal cortex, which are concerned with the initiation and control of movement. Degeneration of the dopamine system produces Parkinson's disease (see Chapter 4).

An evaluation of the DH

- Overall, the evidence is inconclusive (Lavender, 2000). For example, there's no consistent difference in dopamine levels between drug-free schizophrenics and normals, nor is there any evidence of higher levels of other metabolites indicating greater dopamine activity (Jackson, 1986). Even if such evidence did exist, this could just as easily be a *result* of schizophrenia as its



cause. Also, if dopamine were found to be a causative factor, this might only be *indirect* (for example, abnormal family circumstances give rise to high levels of dopamine which, in turn, trigger the symptoms (Lloyd *et al.*, 1984).

- It's unlikely that any problems with dopamine production/receptivity will prove to be the basic biochemical abnormality underlying all forms of schizophrenia – although it may play a crucial role in some forms (Jackson, 1990). According to Lavender (2000):

> ... if schizophrenia is not a clearly identifiable syndrome but an umbrella term covering a range of symptoms with unclear onset, course, and outcome, then it is obvious that much of the work investigating a specific biological basis will inevitably be inconclusive. So far, this appears to be the case.

As Bentall (1990) argues, perhaps the time has come to concentrate on specific symptoms, before trying to find the biochemical cause(s).

- The dopamine hypothesis cannot be a complete explanation For example, it takes several weeks for antipsychotics gradually to reduce positive symptoms, even though they begin blocking D2 receptors very quickly (Davis, 1978). Their eventual therapeutic effect may be due to the effect this blockade has on *other* brain areas and neurotransmitter systems (Cohen *et al.*, 1997).
- Antipsychotics seem to be effective in controlling positive symptoms, and where symptoms come on dramatically. But for patients whose symptoms appear gradually, and in whom negative or disorganised (cognitive) symptoms predominate, they're much less effective. The latter may stem from *reduced* dopamine levels in certain parts of the brain (such as the frontal lobes) and increased levels in others (such as the limbic system) (Javitt & Coyle, 2004).

The brain and schizophrenia

- Newer antischizophrenic drugs implicate *serotonin*. Serotoninergic neurons are known to regulate dopaminergic neurons in the *mesolimbic pathway* (MLP: see below and Figure 44.6). So, dopamine may be just one piece in a much more complex jigsaw (Davison & Neale, 2001; Javitt & Coyle, 2004).
- Focus has shifted recently to deficiencies in *glutamate*, a neurotransmitter found in almost every part of the human brain. It's known that *angel dust* (PCP, or phencyclidine) induces symptoms that resemble the full range of schizophrenic symptoms (see Chapter 8). At the molecular level, PCP impairs the function of the brain signalling systems that rely on glutamate, the brain's major *excitatory* neurotransmitter (see Chapter 4). More specifically, it blocks the action of a form of glutamate receptor called the NMDA receptor, which plays a crucial role in brain development, learning, memory and neural processing in general. It also plays a role in regulating dopamine. Blocking NMDA receptors produces the same disturbances of dopamine functioning as typically occur in schizophrenia. So, NMDA receptor dysfunction, by itself, can account for *both* negative and disorganised symptoms, and the dopamine abnormalities at the root of positive symptoms (Javitt & Coyle, 2004).
- Improved technologies for studying neurochemical factors in humans, plus inconsistent data, have led to the claim that what schizophrenics have is an excess of dopamine *receptors*, or that their D2 receptors are *oversensitive*. This refined DH is based on several postmortem and PET scan studies. Having too many – or oversensitive – receptors is functionally equivalent to having too much dopamine itself, and seems to be associated mainly with *positive* symptoms (Davison & Neale, 2001).
- An excess of dopamine located in the *mesolimbic pathway* (MLP) seems to be most relevant to understanding schizophrenia. The therapeutic effects of antipsychotic drugs on the positive symptoms occur by blocking D2 receptors there. The *mesocortical pathway* (MCP) begins in the same brain region as the MLP, but projects to the prefrontal cortex (PFC) (see Figure 44.6).

The genetic theory of schizophrenia

As Table 44.5 shows, relatives of patients with schizophrenia (proband or index cases) have a greater risk of being diagnosed themselves as the genetic relationship becomes closer. This was confirmed by Kendler *et al.* (1996).

As with intelligence (see Chapter 41), *family resemblance studies* confound genetic and environmental influences. In other words, there's no way of telling whether the correlation between the risk of developing schizophrenia and degree of family resemblance/blood tie is due to the greater genetic similarity or the greater

Table 44.5 Summary of major European family and twin studies of the genetics of schizophrenia (based on Gottesman *et al.*, 1987; Gottesman, 1991)

Relationship to proband	Percentage with schizophrenia
Spouse	1.00
First cousin	2.00
Grandchild	2.84
Niece/nephew	2.00–2.65
Child	9.35
– with one schizophrenic parent	6.00
– with two schizophrenic parents	46.00
Sibling	7.30–10.00
Dizygotic (DZ) twin	12.00–12.08
Monozygotic (MZ) twin	44.30
Monozygotic twin reared apart (MZA)	58.00

similarity of environments. The two major alternative designs, *twin and adoption studies,* both face problems of their own. (These were discussed in detail in Chapter 41, and the same issues apply here). In addition to all the *methodological* problems faced by twin and adoption methods, they presuppose that schizophrenia is a distinct syndrome which can be reliably diagnosed by different psychiatrists (but see Chapter 43).

Twin studies

ASK YOURSELF...

- What conclusions can you draw from Table 44.6?

As Table 44.6 shows, there's a wide variation in the concordance rate for schizophrenia in different studies, for both MZs and DZs, suggesting that different countries use different criteria for diagnosing schizophrenia (see Chapter 43). By the same token, if the highest concordance rate for MZs is 69 per cent, this still leaves plenty of scope for the role of environmental factors. If schizophrenia were totally genetically determined, then we'd expect to find 100 per cent concordance rate for MZs: if one member of an MZ pair has schizophrenia, the other twin should also have it in every single case. In fact, most diagnosed cases *don't* report a family history (Frith & Cahill, 1995).

Nevertheless, the average concordance rate for MZs is five times higher than that for DZs (50 per cent and 10 per cent, respectively: Shields, 1976, 1978). A more precise estimate for the relative importance of genetic and environmental factors comes from studies where MZs reared apart are compared with MZs reared together: according to Shields (1976, 1978), the concordance rates are quite similar for the two groups,

Table 44.6 Results of published schizophrenia twin studies (adapted from Joseph, 2003)

		Pairwise concordance rates					
		Identical twins			Same sex non-identical twins		
Author (year)	**Country**	**N**	**C**	**per cent**	**N**	**C**	**per cent**

N = number of twin pairs studied, C = number concordant

suggesting a major genetic contribution (but see Chapter 41).

Adoption studies

Adoption studies arguably provide the most unequivocal test of genetic influence, because they allow the clearest separation of genetic and environmental factors. They've largely replaced twin studies as the most frequently cited evidence in favour of the genetic theory of schizophrenia (Joseph, 2003).

Heston (1966) studied 47 adults born to schizophrenic mothers and separated from them within three days of birth (the 'adoptees method' (AM): Joseph, 2003). As children, they'd been reared in a variety of circumstances, though not by the mother's family. They were compared (average age 36) with controls who were matched for circumstances of upbringing, but where mothers hadn't been schizophrenic: five of the experimental group but none of the controls were diagnosed as schizophrenic.

Rosenthal *et al.* (1971) reported on a series of studies begun in 1965 in Denmark, which has national registers of psychiatric cases and adoptions. They confirmed Heston's findings, using children separated from schizophrenic mothers, on average at six months.

KEY STUDY 44.1 The Danish–American Adoptees' Family Study (Kety *et al.*, 1968, 1975)

- In a major adoption study of schizophrenia, Kety *et al.* used a different design from Heston and Rosenthal *et al.*
- Two groups of adoptees were identified, 33 of whom had schizophrenia and a matched group that didn't. Rates of disorder were compared in the biological and adoptive families of the two groups of adoptees (the 'adoptees' family method (AFM): Joseph, 2003).
- The rate was greater among the biological relatives of the schizophrenic adoptees than among those of the controls, a finding that supports the genetic hypothesis.
- Further, the rate of schizophrenia wasn't increased among couples that adopted the schizophrenic adoptees, suggesting that environmental factors weren't of crucial importance (Gelder *et al.*, 1989).

The reverse situation was studied by Wender *et al.* (1974), who found no increase among adoptees with normal biological parents but with a schizophrenic adoptive parent (the 'cross-fostering method' (CFM): Joseph, 2003). Gottesman & Shields (1976, 1982), reviewing adoption studies, conclude that they show a major role for heredity.

Conclusions: the nature and nurture of schizophrenia

- Perhaps the most reasonable conclusion is that there's converging evidence, from multiple sources, implicating genetic factors in the aetiology of schizophrenia. Its heritability seems to be comparable to that of any medical condition known to have a major genetic component, such as diabetes, hypertension, coronary artery disease, and breast cancer (Lilienfeld, 1995).
- However, the precise mode of inheritance remains controversial (Frith & Cahill, 1995; Lilienfeld, 1995). The most popular current view is the 'multifactorial' (*polygenic*) model: a number of genes are involved which determine a predisposition, which then requires environmental factors to trigger the symptoms of the illness. This is referred to as a *diathesis* (i.e. predisposition) –*stress model*.
- Zubin & Spring (1977), for example, claim that what we probably inherit is a degree of *vulnerability* to exhibiting schizophrenic symptoms. Whether or not we do depends on environmental stresses which may include viral infections during pregnancy (especially influenza A), severe malnourishment during pregnancy, birth injury or difficult birth, being born in winter, as well as 'critical life events' (see Chapter 38).
- According to Claridge & Davis (2003), individual studies have reported concordance rates for MZs ranging from zero to 90 per cent. Yet 50 per cent is often quoted. Claridge and Davis think this is suspicious:

> ... Is it possible that the value of 50 per cent now generally quoted is merely some average of a range of heritabilities for entirely different psychotic disorders, different varieties of schizophrenia, or just illnesses of different severity? ...

Heritabilities do vary in proportion to the judged severity among the cases sampled (Gottesman & Shields, 1982). More intriguing – and rather puzzling – is a finding relating to the *same* sets of twins diagnosed on two separate occasions: once according to FRSs, then again using broader criteria. On the broader criteria, the concordance rate for MZs was 50 per cent, but on FRSs, it was zero! (Farmer *et al.*, 1987; McGuffin *et al.*, 1987). According to Claridge & Davis (2003):

> ... This tends to suggest that, despite their convincingly 'psychotic' appearance, first rank symptoms do not tap directly into whatever is inherited in schizophrenia; instead they may indeed be secondary elaborations of some more fundamental (inherited) cognitive processes, along the lines visualized by Bleuler.

- According to Claridge & Davis (2003):

> ... the contribution of genetic influences is one of the few factual certainties about schizophrenia. Even in the absence of the discovery of specific genes, this is clear from kinship data ...

But, as the *diathesis–stress model* maintains, any inherited factors can account only for a greater vulnerability or likelihood of developing schizophrenia. They don't *guarantee* that the vulnerable individual will actually become

schizophrenic. So, just as Claridge and Davis are certain that genetic factors are involved, they're equally certain that the genetic data tell us that environmental factors must also be important. But these can be interpreted as *biological* factors (viral infections, birth complications and the like: see above) or as *social*. For example, Tienari (1991) examined the rate of schizophrenia in Finnish people who'd been adopted and whose biological mothers were schizophrenic. As predicted, having a biological mother with schizophrenia increased the rate of schizophrenia in the adoptees, even if they were adopted by non-schizophrenic families. But the schizophrenic gene revealed itself only if the adoptive family was psychologically disturbed in some way. So even vulnerable individuals could be protected from schizophrenia if their family of rearing was healthy.

- According to Joseph (2003), it's far easier to say that some people have a genetic predisposition than to create a society where children don't grow up in seriously disturbed families. As he says:

  > ... Genetic theories in psychiatry tend to blame the victim and let society off the hook, and in this way help support the status quo ... as ... Lewontin once observed, the question revolves around whether we see an individual as a problem for society, or society as a problem for the individual.

Laing and existential psychiatry

One group of British psychiatrists who most certainly didn't let society off the hook and saw society as a problem for the individual, were Laing, Cooper and Esterson, during the 1950s and 1960s. They were united in their rejection of the medical model of mental disorder. Like Szasz, they denied the existence of schizophrenia as a disease entity, and instead saw it as a metaphor for dealing with people whose behaviour and experience fail to conform to the dominant model of social reality. They thus spearheaded the *antipsychiatry movement* (Graham, 1986).

R.D. Laing (1927–1989)

Heather (1976) identifies three major landmarks in the development of Laing's thought, corresponding to the publication of three major books.

- In *The Divided Self* (1959), Laing tried to make sense of schizophrenia by 'getting inside the head' of a schizophrenic, trying to see the world as the schizophrenic sees it (the *psychoanalytic model*). This *existentialist analysis* retained the categories of classic psychiatry, but proceeded from the assumption that what the schizophrenic says and does are intelligible if you listen carefully enough. Laing found a split in the schizophrenic's relationship with the world and with the self: s/he experiences an intense form of *ontological insecurity,* making everyday events a threat to his/her very existence.
- In *Self and Others* (1961), Laing proposed the *family interaction model.* Schizophrenia can only be understood as something which takes place *between* people (*not* inside them). To understand individuals, we must study not individuals but interactions between individuals, and this is the subject matter of *social phenomenology* (see Chapter 22).

The family interaction model was consistent with research in America, especially that of Bateson *et al.* (1956), which showed that schizophrenia arises within families which use 'pathological' forms of communication, in particular contradictory messages (*double-binds*). For example, a mother induces her son to give her a hug, but when he does she tells him 'not to be such a baby'. Laing & Esterson (1964) presented eleven family case histories (in all of which one member becomes a diagnosed schizophrenic), in order to make schizophrenia intelligible in the context of what happens within the patient's family and, in so doing, to undermine further the disease model of schizophrenia.

- In *The Politics of Experience* (1967), two new models were presented. The *conspiratorial model* maintains that schizophrenia is a label, a form of violence perpetrated by some people on others. The family, GP, and psychiatrists conspire against schizophrenics in order to preserve their definition of reality (the status quo). They treat schizophrenics as if they were sick, imprisoning them in mental hospitals, where they're degraded and invalidated as human beings.

According to the *psychedelic model,* the schizophrenic is an exceptionally eloquent critic of society, and schizophrenia is 'itself a natural way of healing our own appalling state of alienation called normality'. Schizophrenia is seen as a voyage into 'inner space', a 'natural healing process'. Unfortunately, the 'natural sequence' of schizophrenia is very rarely allowed to occur because, says Laing, we're too busy treating the patient.

In the past 30 years, eating disorders (EDs) have become widespread in western industrialised societies. This may be related to the overabundance of food, but it's likely to be influenced by societal norms that link attractiveness to being thin (APA, 1994). Indeed, the popular and scientific assumption is that the preoccupation with thinness and dieting rampant in western societies is a direct cause of eating disorders. However, according to Fedoroff & McFarlane (1998):

> ... it is well established that eating disorders are multidetermined and that culture is only one of many factors that contribute to the development of eating disorders ...

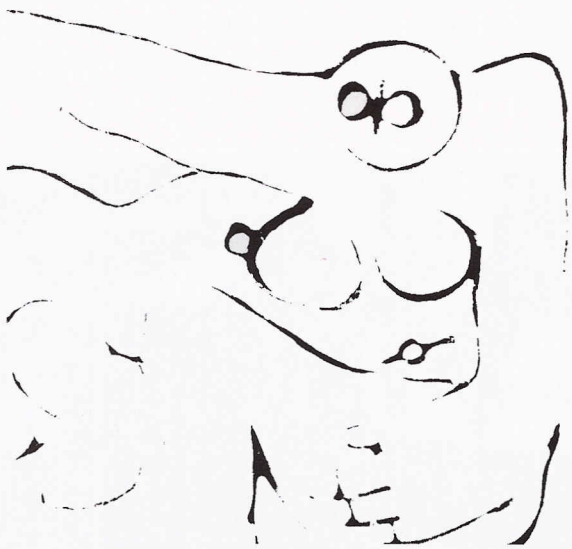
Furthermore:

> ... cultural factors can only be understood as they interact with the psychology and biology of the vulnerable individual ... a culture cannot cause a disorder ...

According to the *dimensional* view, the full-blown ED is the end-point along a continuum that begins with normal dieting, advances to excessive concern about weight and the emergence of some clinical symptoms, and finally a severe, pathological illness. In recent years, this viewpoint has become more popular – even in mainstream psychiatry. So, it's widely agreed that the EDs are most appropriately regarded as a 'spectrum of pathology', rather than discrete disease entities. Although we continue to use DSM diagnostic criteria and terminology for convenience, in practice assessment typically reflects the dimensional view, and patients with milder forms are treated alongside more serious cases (Claridge & Davis, 2003).

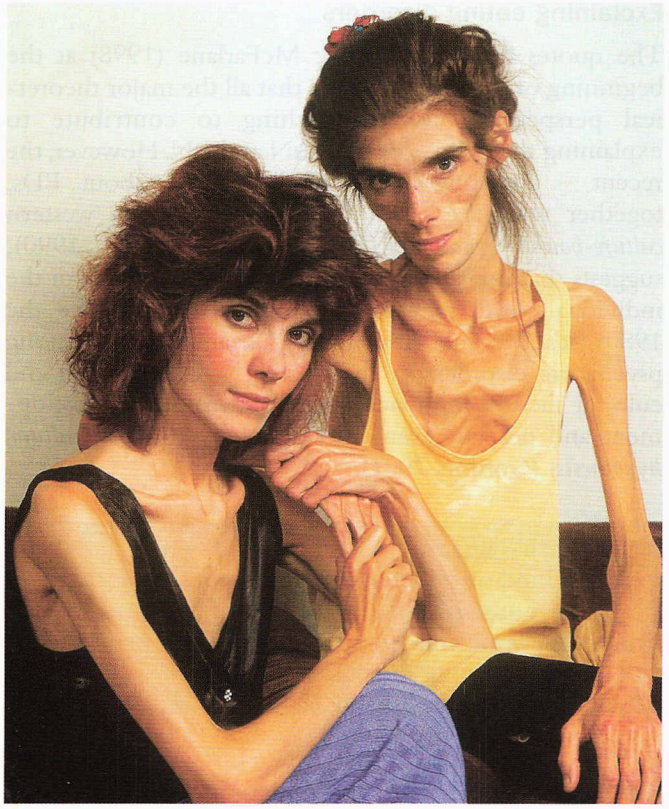
Anorexia nervosa

Anorexia nervosa (AN) (literally, 'nervous lack of appetite') usually begins in adolescence (16–17) after the patient (90–95 per cent of whom are female) has become over-concerned about 'puppy fat' and has begun to diet. This dieting often masquerades as 'vegetarianism' (Lipsedge, 1997b) and progresses to a relentless attempt to achieve what is in fact an abnormally low body weight. AN affects 0.5–1 per cent of adolescent and young adult women (Claridge & Davis, 2003). Up to one third also describe episodes of uncontrollable overeating (binge-eating/bulimia nervosa: see below). There's also evidence of an increase in cases of AN among males (Seligmann *et al.*, 1994). Where the age of onset is 8–14, about 25 per cent are boys (Frude, 1998).



Box 44.9 DSM-IV-TR criteria for anorexia nervosa

- Refusal to maintain body weight at or above a minimally normal weight for age and height (e.g. weight loss leading to maintenance of body weight less than 85 per cent of that expected; or failure to make expected weight gain during periods of growth, leading to body weight less than 85 per cent of that expected).
- Intense fear of gaining weight or becoming fat, even though underweight.
- Disturbance in the way in which one's body weight or shape is experienced, undue influence of body shape and weight on self-evaluation, or denial of the seriousness of current low body weight.
- In post-menarchal females, amenorrhoea, i.e. the absence of at least three consecutive menstrual cycles. (A woman is considered to have amenorrhoea if her periods occur only following hormone, e.g. oestrogen administration.)



Specific types

- *Restricting type*: During the episode of anorexia nervosa, the person does not regularly engage in binge eating or purging behaviour (i.e. self-induced vomiting or the misuse of laxatives or diuretics).
- *Binge eating/purging type*: During the episode of anorexia nervosa, the person regularly engages in binge eating or purging behaviour (i.e. self-induced vomiting or the misuse of laxatives or diuretics).

The restricting type is what we most commonly associate with AN. Both the quantitative and qualitative value of food eaten is systematically reduced over time, producing an escalating state of malnutrition and loss of energy. But, as Claridge & Davis (2003) observe, the binge eating/purging type sounds more like bulimia nervosa (BN) than it does the restricting type of AN. So, the DSM classification seems quite arbitrary, and some researchers have questioned whether these really are separate disorders

An anorexic patient's painting of how she sees herself at 'normal' weight – obese, ugly and resentful (from Crisp, 1980)

The much publicised English anorectic twins, Samantha and Michaela Kendall. Despite receiving treatment in the USA, Samantha eventually died. Michaela died three years later

(Mitchell & McCarthy, 2000). The only real difference between restricting type AN and BN is the patient's *body weight* (the latter's is either within normal limits or actually *over*). DSM has chosen to use body weight (in practice, *body mass index,* or BMI) as the unifying characteristic for the AN subtypes, instead of classifying EDs according to their *psychobehavioural* similarities.

Menstrual status is probably the most useful marker of the distinction between AN restricting type and BN. *Amenorrhoea* often occurs early in the development of the disorder, *preceding* any obvious weight loss in about 20 per cent of cases, Depression, lability of mood, social withdrawal and lack of sexual interest are all common. Some patients have signs that are secondary to the low food intake, including constipation, low blood pressure, bradycardia (slow heart rate), sensitivity to cold and hypothermia (Gelder *et al.*, 1999). Those whose dieting progresses to AN (the vast *minority*) are more likely to have low self-esteem, and prevalence is increased among groups for whom weight and physical appearance are particularly relevant, such as ballet students and models (see Critical Discussion 44.6, page 803).

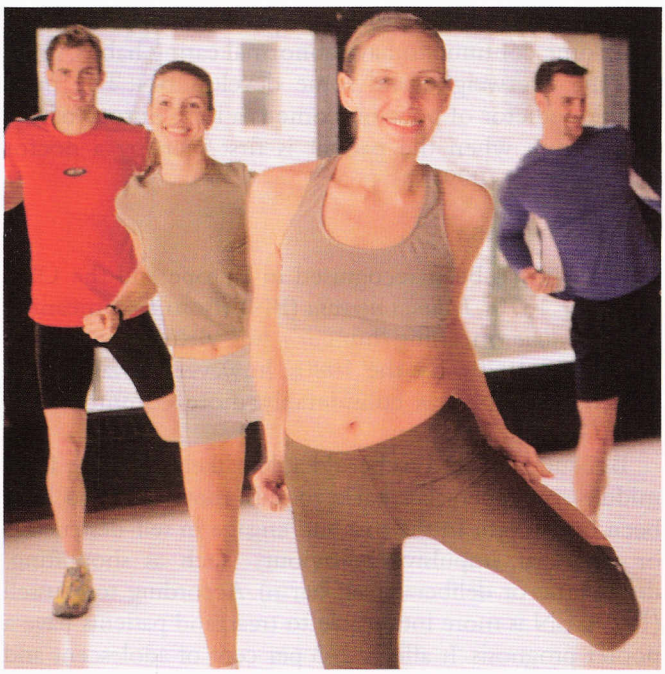
AN has the highest mortality rate of *any* psychiatric disorder (including depression and alcoholism). According to the Eating Disorders Association (EDA), mortality is 13–20 per cent (Waterhouse & Mayes, 2000), death arising from both the effects of starvation and suicide.

Among those with improved weight and menstrual function, some continue to have abnormal eating habits, some become overweight, and some develop BN. The most useful predictor of poor outcome is a long history of AN at the time when the patient is first seen by a doctor (Gelder *et al.*, 1999).

Bulimia nervosa

While AN has been recognised in Europe and the USA since the 1870s, *bulimia nervosa* (BN) (from *bous* meaning 'ox' and *limos* meaning 'hunger') was virtually unknown before the 1970s. By the 1980s, however, it was widely agreed that BN was considerably more common than AN (Gordon, 2001).

BN sufferers tend to be older, less likely to come from middle- or upper-class backgrounds, more likely to have been overweight in the past and engage in self-destructive or antisocial, impulsive behaviours (such as shoplifting, drug abuse or deliberate self-harm). According to Russell (1979), BN is more intractable to treat, and patients have a poorer prognosis. It affects 2–3 per cent of adolescent and young adult women (Claridge & Davis, 2003).



Box 44.10 DSM-IV-TR criteria for bulimia nervosa

- Recurrent episodes of binge eating. An episode of binge eating is characterised by both (a) eating in a discrete period of time (e.g. in any two-hour period) an amount of food that is definitely larger than most people would eat in a similar period of time (taking into account time since last meal and social context in which eating occurred); and (b) a sense of lack of control over eating during the episodes (e.g. feeling that one can't stop eating or control what or how much one is eating).
- Recurrent use of inappropriate compensatory behaviour to avoid weight gain, e.g. self-induced vomiting.
- A minimum average of two episodes of binge eating and two inappropriate compensatory behaviours a week for at least three months.
- Self-evaluation is unduly influenced by body shape and weight.
- The disturbance does not occur exclusively during episodes of anorexia nervosa.

Specific types

- *Purging type*: These individuals regularly purge after binge eating via self-induced vomiting or abuse of laxatives.
- *Non-purging type*: These individuals do not engage in self-induced vomiting or laxative abuse. Some may use compensatory methods of dieting and exercising.

Depression is common (mainly secondary to the ED), and there's considerable lability of mood. It's not uncommon for sufferers to contemplate suicide after binging, or to actually attempt suicide. While denial is a common feature of AN, BN sufferers are usually well

Regular exercise can be a way of concealing an eating disorder through a socially highly valued activity

aware that they have a serious problem and require help (Mitchell & McCarthy, 2000). However, the non-purging type is more likely to follow a binge with periods of fasting or excessive physical activity. This probably represents the most secretive and difficult to recognise type, since exercise is so highly valued in western society. Because of all the known benefits of regular exercise (see Chapter 12), the exercising bulimic is likely to be seen by even close friends and family as the picture of health. By contrast, the anorectic who exercises obsessively will be conspicuous because of her emaciated appearance (Claridge & Davis, 2003). Unlike anorectics, bulimics don't 'look' bulimic.

Episodes of bulimia may be precipitated by stressful events, the breaking of self-imposed dietary rules, or they may be planned. It's the extreme lack of control over eating that distinguishes BN from AN. The binge initially provides pleasurable relief from the urge to eat and other kinds of tension. But this is soon followed by guilt and disgust. Repeated vomiting causes potassium depletion, which induces weakness, cardiac arrythmia (irregular heart rhythms), and renal damage. Urinary infections and epileptic seizures may also occur (Gelder *et al.*, 1999). Tooth enamel becomes eroded by the gastric acid brought up by vomiting.

ASK YOURSELF...

- Based on these criteria for diagnosing AN and BN, do you think they represent exaggerations of 'normal' eating/dieting behaviours, or are they qualitatively different?

Explaining eating disorders

The quotes from Fedoroff & McFarlane (1998) at the beginning of this section imply that all the major theoretical perspectives have something to contribute to explaining the origins of both AN and BN. However, the recent – and ongoing – public debate about EDs, together with the claim that they may be a western *culture-bound syndrome* (CBS) (e.g. DiNicola, 1990), suggests that explanations at the cultural (rather than the individual) level may be the place to start. Since the 1980s, it's become clear that EDs are unique among psychiatric disorders in the degree to which social and cultural factors influence their epidemiology, development and perhaps even their aetiology (the *sociocultural hypothesis*) (Gordon, 2001).

ASK YOURSELF...

- What kind of evidence would support the sociocultural hypothesis?
- What specific cultural factors would you expect to be particularly influential?

Are EDs universal? Are the causes universal?

While many studies have found evidence of common symptomatology as described by DSM and ICD in non-western societies, others have proposed that some symptoms don't appear in some non-western cultures. For example, an intense fear of fatness and body image disturbance aren't typical of AN patients in Hong Kong and India, and their reasons for refusing food are more likely to be linked to somatic symptoms, such as abdominal bloating and fullness. They're also much less likely to display bulimic symptoms. In non-western countries, weight loss is often achieved purely by dietary restriction, rather than purging behaviours (Federoff & McFarlane, 1998). Although 'fat concern' has become a collective experience in the modern world (western and non-western), the *experience* of people with AN is extremely diverse (Lee, 2001).

Although emaciation, food refusal, and amenorrhoea are universal symptoms of AN, it's important to evaluate symptoms in their cultural context. For example, is fasting a culturally sanctioned expression of religious piety (as in Middle Eastern countries), or is it a symptom of an underlying disorder? All the screening and diagnostic instruments have been developed in Europe and North America, and are based directly on western concepts of abnormal eating. Consequently, patients who don't fit the model, but who may well be showing cultural diversity in the expression of a psychiatric disorder, will be ignored (Kleinman, 1987). Similarly, Lee (2001) argues that when the DSM approach is applied to AN, fat phobia becomes the 'core' symptom. This means that:

... patients who do not fit into this constructed (and constricted) template are conveniently discarded as unreal, atypical or simply dishonest deniers ...

This makes the detection of reliable cross-cultural differences very difficult.

Subcultural differences

According to Federoff & McFarlane (1998), the majority of the evidence from surveys and clinical reports indicates that the prevalence of AN and BN in non-white groups is lower than among whites. An interesting exception to this consistent finding is described in Key Study 44.2.

KEY STUDY 44.2 BN among Asian and non-Asian girls in England (Mumford & Whitehouse, 1988; Mumford *et al.*, 1991)

- Mumford and colleagues compared 204 Asian and 355 white schoolgirls in the north of England.
- Those whose self-report measures indicated a possible eating disorder were interviewed. A total of 3.4 per cent of the Asian girls and 0.8 per cent of the white girls met the DSM-III-R (1987) criteria for BN.
- Contrary to expectations, Asian girls from traditional families were *more* likely to develop an ED than those from more westernised families. The researchers suggest that the tensions of living in a traditional Asian family within a western culture might be responsible.

The conflict faced by these girls from traditional Asian families is mirrored, on a far greater scale, by women in general, and women living in countries undergoing major social and political change in particular.

CRITICAL DISCUSSION 44.5 EDs and women's identity

- The incidence of EDs appeared to rise sharply in the USA and UK, and many European countries, during the mid-to-late 1960s, then in accelerating fashion into the 1970s and through the late 1980s. Some have described this as a modern epidemic, which has coincided with a number of sweeping changes in western societies during that period (Gordon, 2001). More specifically:

  ... because eating disorders affect mainly females and revolve around issues of identity and body image, it is not surprising that observers have linked the rise of eating disorders in the West with the crises of female identity and the forces impinging on women that followed the cultural upheavals of the 1960s ... (Gordon, 2001)

- According to Wolf (1991):

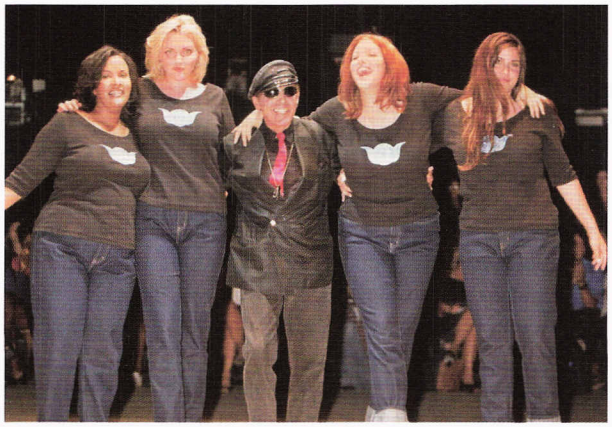
  ... As women have moved in increasing numbers into the spheres of education and work around the globe, expectations for achievement and performance have sometimes conflicted sharply with insistent demands for traditional postures of dependency and submissiveness ...

  These contradictory pressures have produced an increased sense of personal uncertainly, self-doubt and powerlessness. The thin body ideal de-emphasises traditional 'feminine' curvaceousness in a society still riddled with sexist stereotypes that associate 'curves' with low intelligence (Silverstein & Perlick, 1995).
- All the evidence suggests that EDs are no longer unique to western societies. For example, Mumford *et al.* (1992) found that English-speaking girls in Lahore, Pakistan, showed similar rates of BN to white schoolgirls in England. Significantly, the Pakistani girls lived in an area where there were many advertisements for slimming clinics and 'keep fit' clubs. They were also from upper social classes, and were more likely to have adopted western lifestyles and values.
- Crucially, there are contradictory pressures that emerge when women begin to have access on a mass scale to education and a more equal role in public life. This may be especially problematic in societies where the transition to a new female role is particularly sudden and conflicts sharply with traditional forces that demand deference to one's family and submissiveness to men (Gordon, 2001).
- In post-apartheid South Africa, the evolving emancipation of women is part of profound changes in the sociocultural environment in general (Szabo & le Grange, 2001):

  ... If the central dynamic of an eating disorder is an identity struggle, then this struggle could be defined as a desire to become more 'western' while at the same time embracing a new found pride in being African, that is, to take pride in one's African culture, psychologically, and literally ...

  The conflict over gender roles may no longer be an exclusive issue for western women (Nasser, 1997), and EDs may be one way in which this search for identity in black South African women is expressed (Szabo & le Grange, 2001).

CRITICAL DISCUSSION 44.6 Can you catch anorexia from *Vogue* magazine?



- In June 2000, the British government held a 'super-waif summit' to debate the causes of eating disorders. In prosperous western societies, where food is abundant, thinness is a status symbol for women. Slimmer physiques reflect upward social mobility, and fat is generally degraded and stigmatised.
- Taking *Playboy* centrefolds and Miss America contestants as representing the western ideal of feminine beauty, Garner *et al.* (1980) found that ideal shape became progressively slimmer from 1959 to 1978. But at the same time, the actual weight and size of the female

population has been *increasing;* this merely adds to the pressure on women to lose weight. This obsession with thinness is so widespread that a moderate degree of body dissatisfaction is now normative among western women (Rodin *et al.*, 1985).

Is the fashion industry contributing to the increased incidence of eating disorders?

- It's widely believed that the female preference for thinness is influenced by its glorification and glamorisation by the media, especially perhaps in women's magazines such as *Vogue*. A recent report by the British Medical Association claims that media images have a major impact on women's perceptions of their bodies, and calls for more 'Sophie Dahls than Kate Mosses' (*Nursing Times,* 2000).
- Interestingly, June 2000's *Marie Claire* published two different covers, one showing a thin Pamela Anderson, the other a curvaceous Sophie Dahl. 65 per cent of readers bought the Dahl cover. It appears that sales of Barbie (in real terms 5 ft 8 in tall and a size 8) are falling, and the supermarket chain Tesco approached Mattel, Barbie's manufacturer, to produce her in a size 14/16 (Robinson, 2000).

Francesco Scavullo and the V girls. Sophie Dahl (second from left) and her fuller-figure colleagues demonstrate that thinness isn't the only ideal/desirable body shape

According to Lee (1993), Chinese in Hong Kong are changing from a traditional low-fat, high-fibre diet to a more westernised, fast-food diet. Obesity is becoming more commonplace among adolescents (see below), as are advertisements for weight-loss clinics and fitness clubs. The incidence of AN and BN is increasing in Japan as the influence of American culture on Japanese society becomes greater (Federoff & McFarlane, 1998).

If fast food is a characteristic of western culture, so is the preferred or 'ideal' appearance of women.

Obesity: the forgotten ED

As serious a problem as AN and BN are, the EDA regards *obesity* as the number one ED among young girls – and the population as a whole. According to figures for 1998, 17 per cent of British men and 21 per cent of women are clinically obese (Waterhouse & Mayes, 2000). According to DSM, obesity isn't an ED.

Overweight and obesity are highly stigmatised, especially for women. This causes an acute tension between the drive for thinness, on the one hand, and the forces that encourage weight gain in the general population, on the other. Gordon (2001) sees this contradiction as centrally involved in the increase in AN and BN. Similarly, Moghaddam (2002) argues that the ideal of thinness conflicts with two other trends: (a) more people now have access to more food; and (b) the mass media are trying to persuade people to consume more:

> To grow up in a western society is to learn to want to control one's weight. Central to this desire for weight control is an ambivalence toward food. On the one hand, food is relatively cheap and easily available, and there is an enormous focus on the joys of cooking and eating. But on the other hand, food has become 'dangerous' and 'public enemy number one'. Food is associated with poor health and even death.

Likewise, Orbach (2004) claims we are, as a culture, confused about eating. For many, food is neither pleasure nor fuel, but something to be watchful, wary and even afraid of.

Vulnerability: the role of individual differences

As powerful as cultural influences are, they cannot tell the whole story. Despite the fact that most women are exposed to pervasive media messages about attractiveness and thinness, the population incidence and prevalence of EDs are relatively low. As Claridge & Davis (2003) put it:

> ... If our glorification of the slender female body was the *principal* cause of eating disorders, we should find a far higher prevalence ... than we do. Whether media images of thinness play a *causal* role, or merely reflect wider cultural standards, is controversial, but it's unlikely that the relationship between the increasing demand for thinness and the rise of EDs is coincidental (Gordon, 2001) ...

According to Freeman (2000), who was hospitalised for four years with AN as a teenager, the media *aren't* the cause of eating disorders. But the current culture of skinniness legitimises the anorectic's belief that she's too fat. Similarly, Claridge and Davis argue that cultural factors 'set the stage', provide the backdrop, heighten awareness and create, for many, the initial motive for dieting:

> ... the power and pervasiveness of advertising are primarily responsible for the normative discontent that many young women – and more recently men – feel about their physical appearance, and for the extraordinary methods they will use to improve their body image. The diet and fitness industries are dual conspirators in this process, and continue to make a fortune from the insecurities and dissatisfaction they have fostered in our society.

However, there's been a recent shift away from explanations of EDs that rely solely on sociocultural factors to those that include a consideration of *individual* factors, including neurophysiological and genetic. A complementary approach is to regard only individuals that are *vulnerable* to these cultural pressures as likely to develop symptoms. Vulnerability may arise through pre-existing anxiety, depression, low self-esteem in childhood and history of weight preoccupation (Bulik, 2001). Other risk factors include *obsessionality*. Perhaps the most consistently reported association is between EDs (especially AN) and OCD (see above).

ASK YOURSELF...

- Can you see any parallels between the vulnerability explanation of EDs and a particular explanation of schizophrenia (see above, page 798)?

We could regard vulnerability as a *diathesis* (a predisposition to develop an ED), with cultural pressures towards thinness (and the ambivalence towards food) providing the 'trigger' (*stress*). As with schizophrenia, the stress on its own isn't sufficient to induce symptoms (otherwise, everyone would have it), but some individuals within the same culture are more likely than others to develop the disorder. Sociocultural factors tell part of the causal story – but not the whole story.

CHAPTER SUMMARY

- While **fear** evolved as an adaptive mechanism, **anxiety** often occurs in the absence of any external threat.
- A **phobia** is an extreme, irrational fear. Most common is **agoraphobia**, followed by **social phobias** and **specific phobias**. **Preparedness** may help explain why some phobias are more easily acquired than others.
- **Obsessions** are recurrent, intrusive thoughts and feelings, often accompanied by **compulsions**, which are repetitive, ritualised behaviours. Their function is to prevent a dreaded event and reduce distress.
- Skinner's **superstition hypothesis** tries to explain how **obsessive-compulsive disorder** (OCD) develops, but is more successful at explaining how it's **maintained**.
- The **pre-frontal cortex** (PFC), **basal ganglia** and **limbic system** are implicated in many **neurobiological/neuropathological** explanations of OCD.
- According to the **serotonin hypothesis** (SH), OCD is caused by abnormally low levels of brain serotonin. Part of the evidence for the SH comes from the successful use of SRI drugs with OCD patients.
- Other, more **cognitive** explanations include Rachman's **thought–action fusion** (TAF) interpretation. TAF represents a form of **psychological vulnerability**, which increases the chances of **misinterpretation**.
- **Body dysmorphic disorder** (BDD) has much in common with OCD. Intrusive thoughts focus on a particular party of the body which the patient finds defective, and compulsion-like behaviours commonly also occur.
- Symptoms of **post-traumatic stress disorder** (PTSD) include both defensive **avoidance/repression** and **flashbacks**.
- PTSD can be seen as a breakdown of the normal stress response. Excessive production of **endorphins** may explain the numbness, and **adrenaline** and **noradrenaline** are thought to destroy cells in the **hippocampus**.
- **Mood** (**affective**) **disorders** can be **bipolar** or **unipolar**. The traditional distinction between **endogenous/psychotic** and **reactive/neurotic depression** is controversial, and causation is no longer implied when a diagnosis of clinical depression is made.
- The higher rate of depression among women is more likely to be due to **non-biological** than hormonal factors. Cultural factors are important in both the expression and diagnosis of depression.
- The major **neurochemical explanation** of depression (the **monoamine hypothesis**/MAOH) is based on the mechanisms of **tricyclics**, **monoamine oxidase inhibitors** (MAOIs) and **specific serotonin reuptake inhibitors** (SSRIs).
- **Learned helplessness theory** (LHT) is the original of three **cognitive** explanations of depression. The realisation that there's more to depression than LH led to LHT's revision in terms of **attribution theory principles**. This, in turn, was modified as **hopelessness theory** (HT).
- **Schizophrenia** is one of the most serious of all mental disorders. Schneider's **first-rank symptoms** (FRSs) are **subjective experiences**, while Slater and Roth's four additional symptoms are **directly observable** from the patient's behaviour.

- An important distinction is made between **positive** (Type I) **symptoms** (the **presence of active symptomatology**), **negative** (Type II) **symptoms** (**lack/poverty of behaviour**) and **disorganised** (or **cognitive**) **symptoms**.
- DSM distinguishes between **disorganised**, **catatonic** and **paranoid** schizophrenia. Other types that have been identified include **simple** and **undifferentiated** (**atypical**).
- Differences between the **brains** of schizophrenics and non-schizophrenics aren't sufficient on their own to allow diagnosis, and evidence for the **dopamine hypothesis** (DH) is inconclusive.
- Considerable evidence from **twin** and **adoption studies** supports the **genetic theory of schizophrenia**; but these are methodologically questionable.
- According to the **diathesis–stress model**, inherited factors can only increase the likelihood that **vulnerable** individuals will become schizophrenic. **Environmental factors** are needed to trigger the symptoms.
- **Anorexia nervosa** (AN) and **bulimia nervosa** (BN) have many symptoms in common. But bulimics are usually of normal weight, are older, are less likely to come from middle-/upper-class backgrounds, and more likely to engage in self-destructive or antisocial behaviours.
- AN and BN are occurring more frequently in developing cultures as they become more industrialised/westernised, which includes changes in diet and attitudes towards desirable physical appearance.
- Eating disorders (EDs) are now far too global to be considered western **culture-bound syndromes** (CBSs), and **obesity** is arguably a greater problem than either AN or BN (though it's not recognised as an ED by DSM).
- EDs may partially be the result of the **ambivalence** towards food in western societies. The **thinness ideal** conflicts with the availability of food, and the promotion of cooking and general consumption of food.
- While there's much support for the **sociocultural hypothesis**, other individual factors are needed to provide a complete account. These may include pre-existing anxiety, depression, low self-esteem and obsessionality.

Links with other topics/chapters

- Fear, as distinct from anxiety, is considered to be adaptive, because it increases *alertness* and *vigilance* (Chapter 7).
- If phobias are maintained through the negative reinforcement produced by avoidance, then it's logical for *behaviour therapy* to force the phobic person to confront the object of their phobia (Chapter 45).
- According to Freud, obsessions are *defensive psychological responses* (that develop during the anal-sadistic stage: Chapter 35) that serve to occupy the mind and *displace* more threatening thoughts. Laughlin (1967), for example, sees the intrusion of obsessive thoughts as preventing the arousal of anxiety, by acting as a more tolerable substitute for a subjectively less acceptable thought or impulse. But it's hard to see what obsessive thoughts of, say, killing someone are a more tolerant substitute for (Chapters 42 and 45).
- Seeing the positives in PTSD, and advocating the expansion of psychology into a science of optimal human functioning, relate to the *aims of psychology as a science*. It also demonstrates that psychology cannot be *value-free* (Chapters 3 and 47).
- In addition to all the traditional roles women have played, as they move into their forties and fifties, they're increasingly having to care for ageing parents and experience the 'full-nest' syndrome (Chapter 38).
- Learned helplessness and the related concept of *control* are relevant to understanding the effects of *stressors* and people's ways of *coping with stress* (Chapter 12).
- Regarding the symptoms – and the whole experience – of depression as universal and culture-free is a form of *ethnocentrism* (Chapter 47).
- The schizophrenic spectrum has its counterpart in the *autistic spectrum* (Chapter 40).
- The validity of twin studies rests upon the *equal environment assumption* (EEA) (Chapter 41).
- Women's *identity* is an issue that arises both in *adolescence* (Chapter 37) and *adulthood* (Chapter 38).
- It's no coincidence that *early adolescence* is currently the most common age for the onset of EDs, especially AN. Also, the age of onset has been decreasing over recent years (it's not atypical to see patients as young as eight: Claridge & Davis, 2003) (Chapter 37).

TREATMENTS AND THERAPIES

INTRODUCTION AND OVERVIEW

As Chapters 43 and 44 have shown, the study of psychological abnormality involves a convergence of psychiatry (a branch of medicine) and abnormal psychology, the latter defined as the scientific study of the causes of abnormal behaviour/mental disorders. In this chapter, the focus is on the *application* of what we know about abnormality in an attempt to help people with psychological problems. The two professional branches of the discipline of psychology whose goals are the maintenance and generation of mental health are *clinical psychology* and (the more recent) *counselling psychology* (Powell, 1995).

Both clinical and counselling psychology draw on the same research findings and range of theoretical approaches that have recurred throughout this book. They also both adopt the *scientist–practitioner model* of helping: the professional helper is guided by, and operates within the framework of, general scientific methods when assessing alternative treatments/therapies (Dallos & Cullen, 1990: see Chapter 3).

While clinical psychologists have traditionally been more influenced by *behavioural approaches* (based on classical and operant conditioning), counselling psychologists (as well as trained counsellors, who may not be psychologists) have been more influenced by the *humanistic approach*. A third, overlapping, professional group are psychotherapists; their methods reflect (to varying degrees) the influence of Freud's *psychoanalysis*.

CLASSIFYING TREATMENTS AND THERAPIES

The relationship between theory and therapy

Where theory has grown out of clinical practice (that is, work with psychiatric patients), theory and therapy are intimately connected (as in Freud's psychoanalysis, and Rogers' client-centred therapy). But behavioural therapies aren't always derived directly from learning theory, which is sometimes unable to account for therapeutic outcomes and certain aspects of abnormal behaviour. Some forms of therapy aren't directly related to any particular theory (e.g. psychodrama and transactional analysis) and, in practice, treatment is often *eclectic,* that is, it combines different techniques from different approaches.

Dimensions along which treatments can be placed

- What most *psychological treatments* have in common is a rejection of the *medical model* (see Chapters 43 and 44). For example, although Freud distinguished between 'symptoms' and 'underlying pathology', the latter is conceived in psychological terms (not genetic or biochemical), and he was concerned with the individual and not the 'disorder'. Although he used diagnostic labels, he did so for linguistic convenience rather than as an integral part of his theories. He focused on understanding his patients' problems in their life context, rather than on clinical labelling (Mackay, 1975).
- One aspect of 'technique' which is profoundly important in the therapeutic relationship is whether or not the therapist makes suggestions and gives advice to the patient (or client). In *directive therapies,* concrete suggestions are made and clients are often instructed to do certain things (such as 'homework' in between sessions, or specific exercises under the therapist's supervision). For example, *behaviour therapy* concentrates directly upon changing people's behaviour (and any desired changes in thoughts and feelings will 'look after themselves'). By contrast, *cognitive–behaviour therapy* (CBT) is aimed directly at thoughts and feelings: clients are instructed to talk to themselves in different ways, to give themselves instructions for behaviour, to write down their distressing and negative thought patterns, and so on.
- *Non-directive therapies* concentrate on making sense of what's going on in the relationship between therapist and client, and on understanding the meanings of the client's experiences (as in *psychoanalysis* and *client-centred therapy*). These are more difficult to describe than directive therapies, because the therapist plays a more passive role:

> ... listen[ing] and tak[ing] part with the client in exploring and experiencing what is going on between them ... (Oatley, 1984)

- *Individual therapies* are conducted between a therapist and a client (one-to-one, face-to-face), and are by far the most popular form of therapy (Feltham, 2000). Most of the major approaches described in this chapter are individual, but some less well-known therapies are, by definition, *group* therapies (see Box 45.1).
- A major development in psychotherapy in the late 1970s and early 1980s was the emergence of *family therapies* and *marital/couple therapy,* reflecting the growing awareness by therapists of the important role played by the client's relationships in the development and maintenance of their problems (Dryden, 1984). Generally, where the problem is seen as interpersonal, family, marital/couple or group therapy is likely to be recommended. But where the problem is seen as 'residing' within the client (intrapsychic), individual therapy would be recommended.

Box 45.1 Non-individual and other arenas/modalities of psychotherapy

- **Family therapy:** A client's difficulties may be considered *systemically* when, for example, there are indications that s/he is 'carrying' the family's secret sexual abuse or unexpressed grief and/or is being scapegoated by other family members. It often involves observation and analysis of sessions via one-way mirrors and video recording.
- **Couple counselling/therapy:** This originated in marriage guidance and marital psychotherapy. It's now offered to unmarried as well as married couples, and to homosexual as well as heterosexual partners. Like individual therapy, it's informed theoretically by different schools of thought. But what's unique to couple counselling is the focus on the *relationship* between the partners. Conflicts over domestic arrangements, interpersonal and sexual issues, children, money, affairs – at conscious and unconscious levels – lead many couples, together or separately, to seek professional help.
- **Peer counselling:** This refers to any kind of counselling or therapy provided on an egalitarian basis, with each peer taking on the role of counsellor and the other as client – then reversing roles.

- **Group therapy:** In groups, clients may discover that others experience similar problems to themselves, that they're accepted by group members (which can generalise into everyday life), that they can give as well as receive help and insights, and that they can draw on others' experiences and perceptions. Groups can act as a *bridge* from individual therapy to everyday living, but group and individual therapy may also take place in parallel. *Psychodrama*, *encounter groups* and *therapeutic communities* are, by definition, group therapies, but psychodynamic and client-centred therapies may be individual or group.
- **Counselling/therapy via other media:** Increasingly, therapy is being offered in non-individual arenas and using alternative media. *Child psychotherapy* is a specialism in its own right, as is *sex therapy* (allied to couple/marital counselling/therapy). The *expressive/arts therapies* include art and drama therapy, psychodrama, dance and movement therapy, therapeutic writing, and use of other media (such as photography). The extent to which *telephone helplines* are used is often played down or regarded, unfairly, as an inferior form of therapeutic help. Increasingly, *therapy-on-line* is being used as an alternative to face-to-face therapy, and this will be enhanced by electronic video communication. Some people *prefer* the safety or convenience of 'distant' counselling (which can also include *bibliotherapy*, or recommended self-help books); others have little choice by virtue of geographical remoteness or limited finances.
- People are often helped by social workers, probation officers, welfare officers, nurses, teachers and others, many of whom have specific counselling training and qualifications. This help may be offered more or less formally, and many clients who accept and benefit from it may not otherwise approach, trust or have access to 'counsellors' or 'therapists'.

(Based on Feltham, 2000)

A group therapy session in progress

What is psychotherapy?

The term 'psychotherapy' is sometimes used to refer to all psychological treatments (as opposed to biological or somatic ones). For example, Holmes & Lindley (1989) define it as:

> The systematic use of a relationship between therapist and patient – as opposed to pharmacological or social methods – to produce changes in cognition, feelings and behaviour.

Similarly:

> Psychotherapy is distinguished from such other forms of psychiatric treatment as the use of drugs, surgery, electric shock treatment and insulin coma treatment ... (Freedman *et al.*, 1975)

Feltham (2000) points out that the 'psychological therapies' (as opposed to biomedical approaches) may be concerned not only with mental health, but also with spiritual, philosophical, social and other aspects of living.

'Psychotherapy' (or 'psychodynamic therapy': see Chapter 2) is also used to refer to those methods based, directly or indirectly, on Freud's psychoanalysis. This approach is also known as *insight therapies* ('talking cures').

In the UK, the tradition has been to contrast psychotherapy with behaviour therapy, while in the USA psychotherapy is used more broadly to include behavioural psychotherapy as well as 'psychodynamic therapy'. However, the UK Council for Psychotherapy (UKCP) has a behavioural psychotherapy section (members of which include the British Association for Behavioural and Cognitive Psychotherapy), as well as a psychoanalytic and psychodynamic psychotherapy section. Other sections include humanistic and integrative psychotherapy, and family, marital and sexual therapy. In 1994, there were 73 member organisations of the UKCP. Special members include the British Psychological Society (BPS) and the Royal College of Psychiatrists, and the British Association for Counselling is an affiliated organisation (Pokorny, 1994). The BPS Division of Counselling Psychology was established in 1994.

At present, anyone in Britain may practise as a psychotherapist and advertise their services as such. Unlike the situation in North America and many European countries, psychotherapy isn't a regulated profession. No formal training or subscription to a code of ethics is required by statute (Aveline, 2002). However, for many years the British Association for Counselling (BAC) (with 19,000 members) has operated a system of individual accreditation of counsellors. In 1996, the counselling organisations launched the UK Register of Counsellors (held by the BAC). In 2000, the BAC changed its name to the British Association for Counselling and Psychotherapy (BACP).

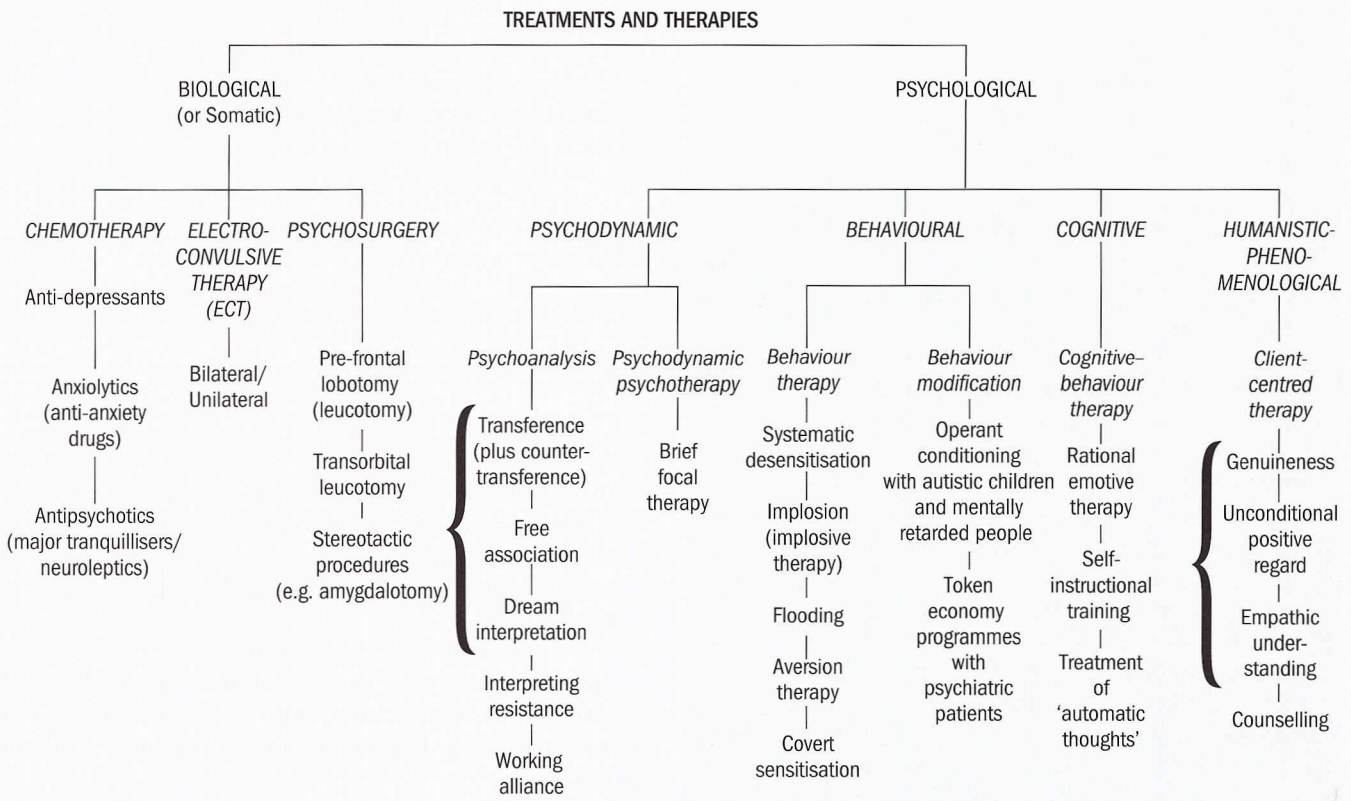

Figure 45.1 Major approaches to treatment and therapy

ASK YOURSELF...

- Looking back at Chapter 44, try to identify (or infer) any principles (or specific details) that would be used by different theoretical approaches in the treatment of mental disorder. (You might find Chapter 2 useful too.)

BIOLOGICAL (SOMATIC) THERAPIES

Chemotherapy

This involves the use of *psychotropic drugs,* that is, drugs designed to affect mainly mental symptoms. Gelder *et al.* (1999) divide these into six groups, according to their primary actions (see Box 45.2). Several also have secondary actions (e.g. antidepressants also reduce anxiety). The focus here will be on the *antidepressants, anxiolytics,* and *antipsychotics.*

Box 45.2 Major categories of psychotropic drugs (Based on Gelder *et al.*, 1999)

Anxiolytics reduce anxiety. Because they have a general calming effect, they're sometimes called *minor tranquillisers*. In larger doses, they cause drowsiness (and so are sometimes called *sedatives*).

Hypnotics promote sleep. Many are of the same type as drugs used as anxiolytics.

Antipsychotics control delusions, hallucinations, and psychomotor excitement in psychoses. They're sometimes called *major tranquillisers* because of their calming effect, and *neuroleptics*, because of their neurological side-effects, such as those resembling Parkinson's disease.

Mood-stabilising drugs are used to prevent the recurrence of affective disorders. One of these is *lithium carbonate* (Lithane or Lithonate), used to treat *bipolar mood disorder.*

Antidepressants relieve the symptoms of depressive disorders, but don't elevate the mood of non-depressed people. They're also used to treat anxiety disorders, including OCD.

Psychostimulants elevate mood, but are used mainly for treating hyperactivity in children.

Antidepressants

The main difference between various kinds of antidepressants is in their side-effects, rather than their effectiveness or speed of action (Gelder *et al.*, 1999). They all increase 5-HT (serotonin) function, and many also increase noradrenaline function. Most can be given just once per day, but they usually 'kick in' only after 10–14 days. They should be withdrawn slowly: sudden cessation can cause restlessness, insomnia, anxiety, and nausea.

Monoamine oxidase inhibitors (MAOIs)

Iproniazid was originally used in 1952 as a treatment for tuberculosis – it elevated patients' mood (without, incidentally, affecting the disease). Iproniazid and related drugs (e.g. *phenelzine* or Nardil) inhibit the activity of an enzyme known as monoamine oxidase (MAO), and gradually increase the activity levels of neurons that utilise noradrenaline (a monoamine) and 5-HT.

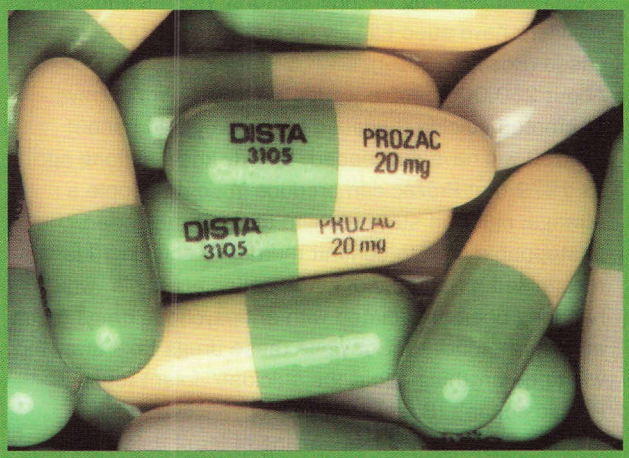
These are generally less effective than tricyclics when used to treat severe depression, and no more effective for mild depression. They're seldom the first choice of treatment, because of their side-effects (including cerebral haemorrhage) and dangerous interactions with other drugs and foodstuffs (although *reversible* MAOIs are safer).

Tricyclics

These are so-named because their basic chemical structure includes three carbon rings. *Imipramine* (Tofranil) and *amitryptyline* were the first to be introduced and are still used as a standard for comparing other antidepressants. They seem to act by blocking the reuptake of dopamine and noradrenaline, but some also block the reuptake of serotonin, others block serotonin alone, and some have no known effect on any of these systems (Hamilton & Timmons, 1995). They're effective in the treatment of both mild and severe depression, and are the first choice of drug in the latter.

However, they have many side-effects, including toxic effects on the cardiovascular system. As a result, they're gradually being replaced by modified tricyclics (such as *lofepramine* and *trazedone*) which cause fewer side-effects (Gelder *et al.*, 1999).

Specific serotonin reuptake inhibitors (SSRIs)



These 'second generation' drugs selectively inhibit the reuptake of serotonin into presynaptic neurons, that is, they make more serotonin available (see Chapter 4). Examples include *paroxetine* and *fluoxetine* (Prozac). They seem to be as effective as tricyclics in treating mild depression, and they're safer for patients with glaucoma and in overdose. Prozac has rapidly become the most commonly prescribed antidepressant medication (Costello *et al.*, 1995), having been taken by more than 38 million people (Boseley, 1999) since its introduction in 1988.

Box 45.3 The Prozac phenomenon: Prozac Nation, UK

- In January 2000, the patent of Prozac's manufacturer (Eli Lilly) expired, meaning that cheap generic versions of the drug are set to flood the international market. This will make 'vitamin P' (as it's been called in the USA) available to those who couldn't previously afford it. This is especially significant given that the World Health Organization (WHO) predicts that depression will become the leading form of ill health across the globe, with an estimated one in three people being affected by 2010 (Munro, 2000).

This would mean 18 million depressed people in the UK alone. According to Munro:

Drugs like Prozac are firmly entrenched in both professional and public minds as the treatment of choice for depression. There is a growing concern that the widespread use of antidepressants is blocking the development of other forms of treatment, such as cognitive therapy. Such a trend could be exacerbated by the increased affordability of fluoxetine ...

Prozac – the world's favourite anti-depressant

- Some feel that an overemphasis on medication has grown from aggressive marketing by drug companies. With Prozac, people for the first time were going to their doctors *asking for* antidepressants *by name*. In 1995, 13.2 million prescriptions were written for *all* types of antidepressant in the UK. In 2002, 26 million prescriptions were written for SSRIs *alone* (Dilner, 2004).
- A recent survey of GPs in the UK found that 80 per cent admit they're overprescribing drugs such as Prozac (and Seroxat: see Critical Discussion 45.1), when patients may simply need someone to talk to. One in three GP appointments now involves patients who are reporting depression (Frith, 2004).
- In 1995, 46,000 prescriptions were given to 16–18-year-olds in full-time education. In 2003, this had risen to 140,000. There's also been a rise of almost 50 per cent in prescriptions for Prozac (and Seroxat) (Townsend, 2004).

ASK YOURSELF...

- One aspect of the controversy surrounding Prozac is its use as a 'designer drug'. Kramer (1993) advocates that everyone could benefit from taking it, since it makes people more assertive and playful, and improves relationships. Kramer believes that in the near future, we'll be able to change our 'self' as easily as we change our clothes ('cosmetic psychopharmacology'). Even if this were possible, do you think it's right?

CRITICAL DISCUSSION 45.1 The Prozac (and Seroxat) controversy: the 'safe' pill that can kill

- Prozac ('vitamin P') was marketed as a wonder drug (Munro, 2000), and its biggest selling-pitch has been that it's almost impossible to kill yourself with an overdose. But since its launch in 1988 in the USA (and in the UK shortly afterwards), there's been a spate of disturbing accounts of violence and suicide committed by people prescribed the drug by their doctors. Victims and families of killers have sued Eli Lilly (see below) in 200 court cases (Boseley, 1999).
- About 250,000 people worldwide taking Prozac have attempted suicide (because of the drug), and about 25,000 will have succeeded. Eli Lilly knew as long ago as 1979 that Prozac can produce in some people a strange, agitated state of mind that can trigger an unstoppable urge to commit murder or suicide. This is a recognised psychiatric disorder called *akathisia*, which has long been associated with antipsychotic drugs (such as chlorpromazine). But while these drugs take away the will to do anything about the suicidal/violent feelings, Prozac doesn't (Boseley, 1999).
- Another SSRI, Seroxat, is proving at least as controversial. Seroxat is among the biggest-selling drugs in the world, and is taken by 600,000–800,000 people in the UK, of whom a significant proportion are under 30 (Laurance, 2004).
- In 2003, Seroxat was banned in the UK for under-18s because of an increased suicide risk. The ban applied to all other SSRIs – except Prozac. According to the Seroxat Users' Group, it's still being prescribed to children and under-18s despite the ban (Townsend, 2004).

How effective are antidepressants?

What this question usually means is: how much more effective are antidepressants than placebos ('dummy drugs', usually inert sugar pills). Fisher & Greenberg (1995) looked at 15 separate reviews of the literature relating to antidepressants, plus two large-scale *meta-analyses* ('studies of studies': see Box 45.10, page 830). Overall, the effectiveness of antidepressants appears to be modest, with a high relapse rate (over 60 per cent) amongst those who respond positively to the drugs but are then taken off them. Their benefits also tend to wane after a few months, even while they're still being taken.

Fisher and Greenberg also discuss the *methodology* of drug trials. In a classic *double-blind design*, neither the patient nor the researcher knows whether the patient is receiving a drug or a placebo. But when the (*inactive*) placebo doesn't produce as many bodily sensations as the drug, participants soon learn to discriminate between them. For example, imipramine causes dry mouth, tremor, sweating, and constipation. These side-effects could be used by those administering the drug/placebo to identify the 'ons' and the 'offs', and they might convey their resulting expectations as to the effects of the drug/placebo to the participants.

For these reasons, *active* placebos (such as atropine), which *do* produce side-effects, are sometimes used. In one review cited in Fisher and Greenberg (1995), 68 studies conducted between 1958 and 1972 which had used an inert placebo were compared with seven which had used atropine. The antidepressant was found to be superior to the placebo in 59 per cent of the former, but in only 14 per cent (one study) of the latter.

Box 45.4 Some other problems with drug trials – and the power of placebo effects

- Depressed people selected for clinical trials usually aren't representative of depressed people as a group. They're moderately depressed, not actively suicidal, and free from other physical and psychiatric illness (Fisher & Greenberg, 1995; Lyddy, 2000). Nevertheless, assigning a depressed person to a placebo condition when there's an effective treatment available is *ethically* problematic.
- Khan *et al.* (2000) studied the potential risk to depressed patients assigned to placebo treatment by examining data from 45 antidepressant clinical trials. The overall incidence of suicide/attempted suicide was low, with no significant difference in risk between active treatments and placebo groups. Interestingly, placebo patients reported substantial symptom reduction (though less than the active treatment groups), and there was a positive correlation between the length of the trial and reduction in symptoms – regardless of the form of treatment group.
- According to Fisher & Greenberg (1995), this isn't surprising, since a response to a placebo is just as biological (i.e. 'real') as a response to an antidepressant. The brain apparently responds in equivalent ways to both talk and drug treatment. Far from being extraneous or less of a biological reality than a chemical agent, placebos have been shown to produce certain effects usually thought to be confined to drugs. For example, they show *dose-level effects* (the larger the dose, the greater the impact), addictions, and toxic effects.
- Because it's impossible to eliminate placebo effects totally, it's impossible to demonstrate that psychotropic drugs have an independent, 'pure' biological impact. Fisher and Greenberg conclude by saying:

  ... Administering a drug is not simply a medical (biological) act. It is, in addition, a complex social act whose effectiveness will be mediated by such factors as the patient's expectations of the drug and reactions to the body sensations created by that drug, and the physician's friendliness and degree of personal confidence in the drug's power ...

Anxiolytics

These are used most appropriately to reduce severe anxiety. They should be prescribed for a short time only (usually a few days, seldom more than two to three weeks), because they can result in tolerance and dependence. Withdrawal effects are reported in people using them for more than six months: the *withdrawal syndrome* includes apprehension and anxiety, tremor, and muscle twitching (see Chapter 8). *Chlordiazepoxide* (marketed as Librium) and *diazepam* (Valium) appeared in the early 1960s, quickly becoming the most widely prescribed drugs of their time. In 1989, for example, there were 21 million prescriptions in the UK alone (Rassool & Winnington, 1993).

Chlordiazepoxide and diazepam are *benzodiazepines* (other examples being temazepam and flurazepam). They were initially called 'minor tranquillisers' (as opposed to the antipsychotic, major tranquillisers), but this terminology became unpopular and they're now simply called *anti-anxiety drugs*. They act by facilitating the activity of GABA (see Chapter 4). As well as anxiolytic, sedative, and hypnotic effects, they have muscle-relaxant and anticonvulsant properties (Gelder *et al.*, 1999).

Antipsychotics

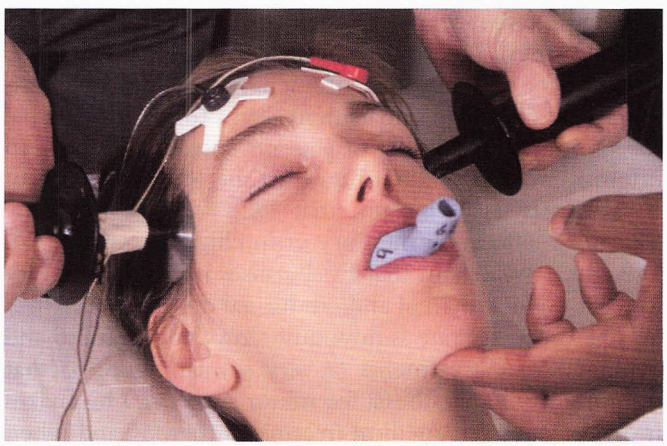
Antipsychotics (or major tranquillisers) such as *chlorpromazine* were originally developed to calm patients facing surgery, and they proved highly effective in reducing the incidence of death from surgical shock. Chlorpromazine (Largactil) and related *phenothiazines* were soon used with psychiatric patients (starting in the early 1950s). They revolutionised psychiatry by allowing the most disturbed schizophrenic patients to live outside a psychiatric hospital, or to reduce their average length of stay. However, many critics have called these drugs 'pharmacological straitjackets'.

They're effective in treating the acute, *positive* symptoms of schizophrenia, such as hallucinations, excitement, thought disorder, and delusions, and they seem to work by blocking the D2 receptor for dopamine. However, they don't touch the *negative* symptoms (emotional blunting, slowness of speech and movement, lack of motivation, social withdrawal: see Tables 44.2 and 44.3, page 791).

Box 45.5 Some side-effects of antipsychotic drugs

- *Extrapyramidal* (EP): *acute dystonia* (involuntary muscle contraction), *akathisia* (inner restlessness, agitation and pacing), *Parkinsonism* (shuffling gait, tremor, expressionless face etc.), and *tardive dyskinesia* (chewing and sucking movements, grimacing, akathisia).
- *Anticholinergic:* dry mouth, blurred vision, low blood pressure (which may cause fainting attacks), constipation, glaucoma.
- *Neurolepticmalignant syndrome:* fluctuating levels of consciousness, hyperthermia, muscular ('lead pipe') rigidity, autonomic disturbances (such as unstable blood pressure, urinary incontinence and tachycardia). While this is rare, it can be life-threatening, and can occur with *any* antipsychotic drug, at any dose, at any time (Hutton, 1998).

(Based on Gelder *et al.*, 1999)



The newer, 'atypical' antipsychotic drugs, such as *clozapine* and *riperidone,* are less likely to cause EP symptoms and may also treat the negative symptoms of schizophrenia. Clozapine is also the first atypical drug shown to be effective in treating patients who have failed to respond to 'typical' antipsychotics such as chlorpromazine (*Effective Health Care,* 1999; Gelder *et al.*, 1999).

Electroconvulsive therapy

In 1938, Cerletti and Bini, two Italian doctors, first gave an electric shock to the brain of a psychiatric patient, on the assumption that if a grand mal epileptic fit is induced (artificially), this should reduce or eliminate the symptoms of schizophrenia. Electroconvulsive therapy (ECT) started to be used widely in the USA from the early 1940s. Ironically, it was found to be more effective for severe depression than schizophrenia, and is now used mainly with depressive patients.

The procedure

The patient is made comfortable on a bed, clothes loosened and shoes and dentures removed. Atropine is given as a routine pre-anaesthetic medication (to dry up salivary and bronchial secretions) and then thiopentone, a quick-acting anaesthetic, followed by a muscle relaxant. A 70–150-volt shock lasting 0.04–1.00 second is then given through electrodes ('paddles') placed on the temples, producing a generalised convulsion lasting for up to a minute (detected by facial and limb twitching). Typically, two to three treatments per week are given for three to four weeks. Less commonly, treatment is given every two

ECT as it is carried out today. Despite the technical improvements, ECT is a highly controversial treatment

to four weeks for six months or longer to prevent relapse (*continuation* or *maintenance ECT*: Bennett, 2003).

Many psychiatrists believe that for severe depression, *bilateral* ECT (one electrode on each side of the head) is preferable, as it acts more quickly and fewer treatments are needed. (This was the common practice up until the 1950s). In *unilateral* ECT, an electrode is applied to the *non-dominant* hemisphere side (the right side for most people) to reduce the side-effects, particularly memory disruption (Benton, 1981).

Contrary to popular belief, ECT is still widely used. Its use began to decline substantially during the 1950s with the introduction of psychotropic drugs, but it was given to 11,340 patients in England and Wales in 1999 (peaking at 28,000 in 1985). Of these, two-thirds were women, 41 per cent were over 65, and 15 per cent were in hospital under section (i.e. involuntarily). It's rarely used in Japan and many other European countries (Johnstone, 2003).

Side-effects

Short-term risks are those associated with being given an anaesthetic and having an epileptic fit. MIND (the National Association for Mental Health) and PROMPT (Protect the Rights of Mental Patients in Therapy) in the UK, and NAPA (Network Against Psychiatric Assault) in the USA, object to it primarily on *ethical* grounds. Some people describe it as a terrifying experience, and regard it as an abusive invasion of personal autonomy (Bennett, 2003). Some experience it as a damaging repeat of earlier traumas (such as physical/sexual abuse), undermining their trust in mental health professionals (Johnstone, 1999; MIND, 2001). Continuing to use ECT in the light of these accounts becomes an ethical issue.

Memory disruption includes retrograde amnesia and impaired ability to acquire new memories (see Chapter 17). But because depression is associated with impaired memory function, it's unclear to what extent ECT itself is responsible (Benton, 1981). The patient is normally confused for up to 40 minutes following treatment, but recall of events prior to treatment gradually returns (although some degree of memory loss may persist for several weeks). The shift from bilateral to unilateral ECT has reduced the amount of memory deficit (Bennett, 2003), but cognitive impairment seems to be unavoidable for an unknown number of patients (a scandal waiting to erupt: Kendell, 1998). Contrary to the Royal College of Psychiatrists' (1997) claim that ECT doesn't have any long-term effects on memory or intelligence, critics (e.g. Breggin, 1997) claim that ECT causes not only memory loss but general mental and emotional dysfunction.

The mortality rate is now quite low (between 3.6 and 9 per 100,000 treatments (a very similar figure to that resulting from anaesthesia for minor surgery). This makes it one of the safest medical treatments there is, and when the number of suicides resulting from depression are taken into account, ECT emerges as 'among the safest medical treatments given under general anaesthesia' (RCP, 1997, in Johnstone, 2003).

However, only one-third of clinics are currently meeting RCP guidelines. For example, staff are poorly trained and supervised, and some clinics use machines that don't allow a sufficiently wide range of current to be delivered. Consequently, patients with a low seizure threshold (which can vary by up to 40 times between different people) may receive too high a dosage (Johnstone, 2003).

How effective is ECT?

ASK YOURSELF...

- Based on methods used in clinical drug trials, how do you think the effectiveness of ECT might be assessed?
- Does this raise similar ethical problems to clinical drug trials?

Sackeim (1989) reviewed controlled comparisons of real and *sham* (simulated or 'dummy') ECT. In simulated ECT, the patient undergoes all aspects of the ECT procedure except that no electrical current is passed through the brain (so no seizure is produced). He concluded that real ECT is significantly more effective than sham ECT. Also, bilateral is slightly more effective than unilateral (but, as we've seen, this is outweighed by the former's greater memory deficits). Sackeim also concluded that ECT is more effective than antidepressant drugs, and probably the most effective available treatment for depression. However the use of medication following ECT can help to prevent relapse.

Current psychiatric opinion in the UK is represented by the RCP *ECT Handbook* (1995), according to which 'ECT ... is an effective treatment in severe depressive illness' and occasionally in other conditions, such as psychosis and mania. In support of ECT, the *Handbook* cites a study by Buchan *et al.* (1992).

KEY STUDY 45.1 Testing the effects of ECT (Buchan *et al.*, 1992)

- Buchan *et al.* compared *sham* (placebo) ECT with real ECT, following up patients four weeks and six months after treatment.
- They concluded that:

(a) ECT did have some beneficial effects, but only with patients whose depression was accompanied by physical retardation or delusions (a very small minority of those diagnosed as depressed) – 'real ECT does not appear to be effective in non-retarded, non-deluded patients'

(b) This benefit was evident at four weeks, but at six months there was no difference between the placebo and treatment groups.

Reviews of the research (e.g. Breggin, 1997) have generally been unable to find any controlled studies showing the benefits of ECT lasting longer than four weeks. Also, the relapse rate is high (RCP, 1995).

How does ECT work?

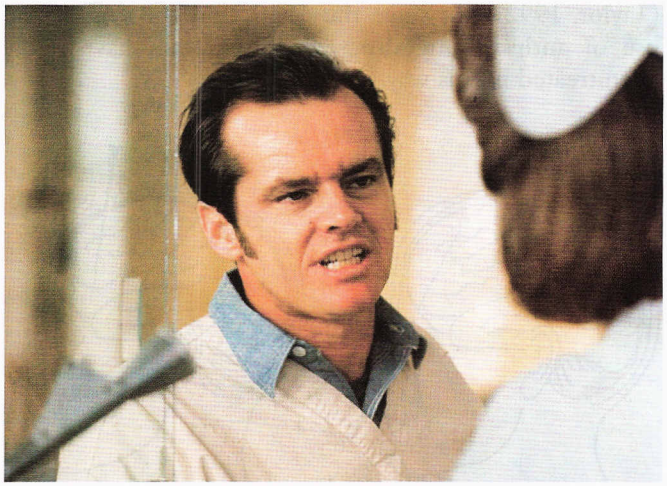
Benton (1981) identifies three explanations of how ECT works.

- Patients come to see ECT as a *punishment* which extinguishes their undesirable behaviour. However, equally unpleasant but subconvulsive shocks (which don't produce a convulsion) aren't effective. This is inconsistent with the 'punishment' explanation.
- *Memory loss* allows the restructuring of the patient's view of life. However, unilateral ECT is intended to minimise memory disruption but is also effective in reducing depression (see above).
- The shock produces a wide range of *biochemical changes* in the brain (e.g. the stimulation of neurotransmitters, including noradrenaline and endorphins: Lilienfeld, 1995). This effect is more widespread than that produced by antidepressant drugs.

According to Abrams (1997: author of the standard textbook *Electroconvulsive Therapy*):

> Modern ECT researchers ... do not have any more of a clue to the relationship between brain biological events and treatment response in ECT than they did at the time of the first edition of this book – which is to say, none at all.

ASK YOURSELF...



- Since we don't know how ECT works (and whether it works), should it be used at all?

Benton (1981) argues that this isn't a reason for not using it: many medical treatments fall into this category (e.g. the use of aspirin in the treatment of headaches). But Szasz (1971) believes that:

> ... electricity as a form of treatment requires the sacrifice of the patient as a person, [and] of the psychiatrist as a clinical thinker and moral agent.

This view is supported by many psychological organisations, including the BPS. In the USA, the National Institute of Health (1985) observes that ECT has been used inappropriately to treat disorders where there's no evidence of its effectiveness. It also notes that the use of ECT to manage disruptive patients has contributed to its public perception as an abusive instrument of *behavioural control* for patients in mental institutions.

According to Breggin (1991, 1997), ECT 'works' by causing *brain damage.* Patients suffer *anosognosia,* a condition in which they deny their psychological and physical difficulties (rather like 'treating' prolonged depression by being permanently drunk). While loss of painful memories may be felt as a relief, this state is sometimes mistaken by staff and patients alike for improvement.

Jack Nicholson as McMurphy and Louise Fletcher as Nurse Ratchet in *One Flew Over the Cuckoo's Nest* (1975)

Psychosurgery

Psychosurgery was pioneered by Moniz, a Portuguese professor of neurology. He was so impressed by the tranquillising effects of lesions to the frontal lobes of monkeys that in 1935 he performed the first *prefrontal lobotomies* (or *leucotomies*) on human schizophrenics. Between 1935 and 1949, Moniz performed about 100 such operations, in which tissue connecting the frontal lobes of the cortex with subcortical brain areas is cut on both sides of the cortex (see Figure 45.2). (Moniz was awarded the Nobel Prize for Medicine in 1949, and was later shot in the spine by one of his lobotomised patients, confining him to a wheelchair for the rest of his life.)

Freeman & Watts (1942) pioneered psychosurgery in the USA, and it's been estimated that 40–50,000 prefrontal lobotomies have been performed in the USA alone since the late 1930s. They modified Moniz's technique by inserting a scalpel either into burr holes drilled through the patient's temple, or through the eye socket (*transorbital leucotomy:* see Figure 45.2). Although their so-called 'standard leucotomy' was far from standardised anatomically, and despite unacceptable side-effects, the procedure was widely used in the UK and other countries (Gelder *et al.*, 1989). For example, in the UK, over 10,000 operations were carried out between 1936 and 1961, about 20 per cent of which involved schizophrenics (Bennett, 2003).

Now, only about 20 operations per year are carried out in the UK, and only for conditions that have proven unresponsive to various alternative treatments. In England and Wales, the use of psychosurgery is governed by the Mental Health Act 1983, which endorses it only as a last resort, requiring the patient's consent. It's still used in other countries, especially Australia and the USA

(Taylor, 1992), but since the 1950s and the widespread use of antipsychotic drugs, schizophrenics have rarely been treated in this way.

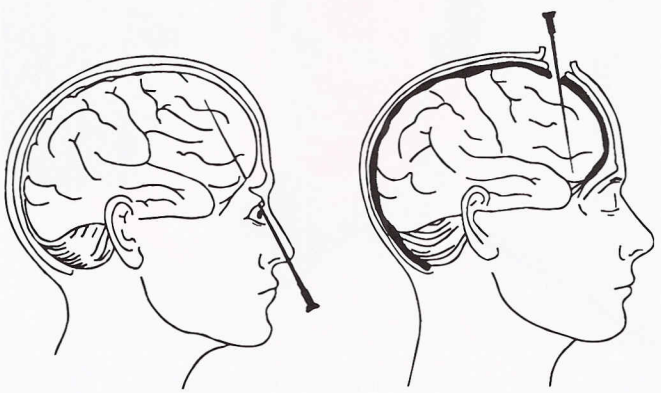


Figure 45.2 The drawing on the left shows the technique used by Freeman and Watts (transorbital leucotomy), a modification of Moniz's classical prefrontal lobotomy/leucotomy (shown on the right)

Box 45.6 Modern forms of psychosurgery

- Today, the older 'blind' operations have been replaced by *stereotactic* procedures, which allow only very small amounts of brain tissue to be destroyed in very precise locations ('fractional operations').
- For example, *amygdalotomy* involves bilateral lesions in the amygdala (destroying the neural circuit connecting the amygdala and the hypothalamus), usually in the treatment of abnormal, intractable aggression.
- The neurosurgeon usually creates lesions with heated electrodes, except in the case of *stereotactic subcaudate tractotomy* (SST). This involves placing radioactive rods into the target area, which destroy parts of the subcaudate area through brief bursts of radioactivity. It's usually used for severe, intractable depression.
- In the UK, a candidate for surgery would have to have made more than two serious suicide attempts, have been clinically depressed for at least 18 years, with the present episode lasting seven years without remission for at least six months, to have received over 30 ECT treatments and unusually large doses of antidepressants. A panel appointed by the Mental Health Act Commission has to be convinced that the person is giving full consent – and that the surgery is likely to be beneficial (Bennett, 2003).

ASK YOURSELF...

- However effective it might be, should psychosurgery *ever* be used – even as a last resort?

(Based on Gelder *et al.*, 1989)

Side-effects

These have included apathy, lethargy, epilepsy, intellectual impairment, aggressiveness and personality change, as well as death. Since the introduction of the more precise sterotactic techniques, mortality has dropped to 1 per 1000 cases, and epilepsy to 1–5 per cent (Jenike, 1998). Also, there's no evidence of reduced intellectual functioning (in fact, many patients perform *better* on psychometric tests than they did before surgery). Nor is there evidence of significant personality changes, despite potential for damage to the frontal lobe (thought to control functions crucial to personality). But the psychometric tests used may not be able to detect subtle frontal lobe deficits – so we cannot rule out the possibility of such damage (Jenike, 1998).

A number of people commit suicide after surgery, but whether this is as a result of the surgery itself, or would have happened anyway, is unclear. One possibility is that patients see the surgery as their last hope, and the outcome is disappointing (Bennett, 2003).

Does psychosurgery work and should it ever be used?

Due to the lack of controlled evaluations, assessments of psychosurgery's effectiveness must be based on follow-up studies of patients who've undergone the procedure. But it's impossible to determine how much improvement would have taken place without surgery (Gelder *et al.*, 1989). While some improvements have been reported:

> ... this intervention is rightfully viewed as a treatment of very last resort, given the permanence of psychosurgery and the poorly understood ways in which it works ... (Davison & Neale, 1994)

Even with modern stereotactic procedures, serious side-effects still occur, and they should only ever be used if all other forms of treatment are considered inappropriate or have been tried and failed (Gelder *et al.*, 1989).

PSYCHOANALYSIS AND OTHER PSYCHODYNAMIC APPROACHES

Freud's model of psychological disorder

In Chapter 42, *neurotic symptoms* were described as compromises between the opposing demands made on the ego by the id and the superego. Symptoms (along with dreams and defences) are expressions of the inevitable conflict which arises from these opposing demands and are, at the same time, attempts to deal with it.

When a person experiences anxiety, the ego is signalling that it fears being overwhelmed by an all-powerful id (*neurotic anxiety*) or superego (*moral anxiety*), and so must mobilise its defences. Anxiety is the hallmark of most neurotic disorders, but except in 'free-floating anxiety', it becomes redirected or transformed in some way (depending on which particular defence is used).

Consequently, the resulting symptom makes it even less likely that the true nature of the problem (i.e. the underlying conflict) will be spotted. *Phobias,* for example, involve *repression* (as do all neuroses), plus *displacement* and *projection* (see Chapter 44).

ASK YOURSELF...

- Try to explain Little Hans' phobia of being bitten by a horse in terms of these three ego defences (see Chapter 35).

Hans' horse phobia could be explained in terms of:

- repressing his jealous anger and hatred felt towards his father
- projecting these feelings onto his father, thus seeing him as a threatening, murderous figure, and
- displacing this perception of his father on to a 'safer' target, namely, horses.

As we noted in Chapter 42, Freud believed that phobic objects symbolically represent the object for which they're a substitute.

Neuroses are *maladaptive solutions* to the individual's problems: they don't help resolve the conflict, but merely help to *avoid* it (both in thought and behaviour). The neurotic's behaviour usually creates its own distress and unhappiness – this is the *neurotic paradox*.

ASK YOURSELF...

- Try to explain neurotic behaviours (and the neurotic paradox) in terms of *learning theory* (i.e. conditioning).

So, in summary, psychoneurotic symptoms are indicative of deep-seated, unresolved, unconscious conflicts, usually of a sexual and/or aggressive nature, stemming from childhood feelings, memories, wishes and experiences. However, the defences used to deal with the conflict are ineffective, creating their own distress and anxiety.

The aims of psychoanalysis

The goals of psychoanalysis can be stated in very broad, abstract terms, such as 'a far-reaching and radical restructuring of the personality' (Fonagy, 1995) and as attempts to provide the client with insight, self-knowledge and self-understanding. More specifically, the basic goal of psychoanalysis is to make 'the unconscious conscious', to undo unsatisfactory defences and, through a 'therapeutic regression' (Winnicott, 1958), to re-experience repressed feelings and wishes, which have been frustrated in childhood, in a safe context, and to express them, as an adult, in a more appropriate way, 'with a new ending' (Alexander & French, 1946).

In relation to the structure of personality model, Freud (1938) believed that the analyst and the patient's weakened ego needed to become allies against the instinctual demands of the id and the conscientious demands of the superego. Analysts who still subscribe to this model aim primarily to extend, through the psychoanalytic process, patients' knowledge of themselves (*insight*), in the hope that this may enable them to make choices that aren't exclusively ruled by neurotic needs – to explore new compromises and more adaptive solutions (Lemma, 2002).

Therapeutic techniques

The role of the analyst

In classical psychoanalysis, the analyst is meant to remain faceless and 'anonymous', not showing any emotion or revealing any personal information. Instead:

> ... The doctor should be opaque to his patients and, like a mirror, should show them nothing but what is shown to him ... (Freud, 1912, in Jacobs, 1992)

With the analyst as an 'ambiguous object' or 'blank screen', the patient is able to project and displace repressed feelings, in particular those concerning parents (*transference*). This process is aided by the client lying on a couch, with the analyst sitting behind, out of the client's (*analysand's*) field of vision. Jacobs (1992) notes that, in practice, Freud often became personally involved in the therapeutic conversation and would explain his thinking to the patient (see below).

Transference and counter-transference

Transference typically goes through a positive phase of emotional attachment to the analyst, followed by a negative and critical phase. According to Freud, this reflects working through the ambivalence experienced in the patient's childhood relationship with his/her parents (Stevens, 1995). According to Thomas (1990), transference has become so central to the theory and practice of psychoanalysis that many analysts believe that making *interpretations* about transference is what distinguishes psychoanalysis from other forms of psychotherapy. When attention is focused on the transference and what's happening in the here and now, the historical reconstruction of childhood events and the search for the childhood origins of conflicts may take second place.

The related process of *counter-transference* refers to the therapist's feelings of irritation, dislike or sexual attraction towards the client. Thomas (1990) maintains that:

> ... In Freud's time, counter-transference feelings... were considered to be a failing on the part of the analyst. These feelings were to be controlled absolutely ... Now, counter-transference is considered an unavoidable outcome of the analytic process, irrespective of how well prepared the analyst is by analytic training and its years of required personal analysis ... most modern analysts are trained to observe their own counter-transference feelings and to use these to increase their understanding of the patients' transference and defences ...

Sigmund Freud's couch (Freud Museum Publications Ltd)

Interpretation and resistance

To enable the client to understand the transference and how it relates to childhood conflicts, the analyst must *interpret* it, that is, tell the client what it means in relation to what's already been revealed about the client's childhood experiences. Because this is likely to be painful and distressing, clients show *resistance*. This may take the form of 'drying up' when talking, changing the subject, dismissing some emotionally significant event in a very flippant way, even falling asleep or arriving late for therapy. All forms of resistance require interpretation.

The working alliance

As important as the analyst's anonymity may be, the '*working alliance*' with the client is just as crucial. According to Jacobs (1984), this consists of two adults cooperating to understand the 'child' in the client. The analyst adopts a quiet, reflective style, intervening when s/he judges the client to be ready to make use of a particular interpretation. This is an art, and *doesn't* involve fitting the client into psychoanalytic theory, as some critics suggest (Jacobs, 1984).

Two other major techniques used to reveal the client's unconscious mind are *dream interpretation* (see Chapter 42) and *free association,* in which the client says whatever comes to mind, no matter how silly, irrelevant or embarrassing it may seem. Freud insisted on the rule of free association, because he realised that however plausible the patients' reasons were for their conscious thoughts and images, these were used by deeper (unconscious) forces demanding to be expressed. Free association is an ideal that patients strive towards – in practice, it's very difficult to share all the contents of our thoughts. Nevertheless, the principle of free association underpins all current psychoanalytic practice (Lemma, 2002).

Both dream interpretation and free association may lead to resistance which, like transference, will in turn be interpreted by the analyst.

CRITICAL DISCUSSION 45.2 The concept of cure. How do you know when to stop?

- According to Jacobs (1984), the goals of therapy are limited by what clients consciously want to achieve and are capable of achieving, together with their motivation, ego strength, capacity for insight, ability to tolerate the frustration of gradual change, financial cost, and so on. These factors, in turn, determine how a cure is defined and assessed.
- In practice, psychoanalysis ranges from *psychoanalytical first aid* (Guntrip, 1968) or symptom relief, to different levels of more intense work. However, Storr (1966) believes that symptom relief is an inappropriate way of perceiving 'cure', partly because symptom analysis is only the start of the analytic process, and also because a majority of clients don't have clear-cut symptoms anyway. Similarly, Fonagy (2000) says that:

  ... Symptom change as a sole indicator of therapeutic benefit must indeed be considered crude in relation to the complex interpersonal processes that evolve over the many hundreds of sessions ...

- Freud himself recognised that psychoanalysis was only likely to be successful if the patient is voluntary, open to change, acknowledges that there's a problem, and is neurotic rather than psychotic (the latter being unable to form a positive transference). Even if the patient possesses these characteristics, fresh neuroses or even the return of the original one cannot be ruled out. Analysis never really ends.
- Indeed, Freud famously claimed that psychoanalysis could help transform 'hysterical misery' into 'common unhappiness'. This is as much as one could hope for, given that intrapsychic conflict is an inevitable part of human life. He also believed that psychoanalysis should be valued for its contributions to a science of human being rather than for any quick results in terms of personality change or the alleviation of neurotic symptoms (Lemma, 2002: see Chapters 2 and 3).

According to Fonagy (2000), evidence from a significant number of before–after studies suggests that psychoanalysis is consistently helpful to patients with milder (neurotic) disorders, and somewhat less consistently so for groups with more severe disorders. Other less well controlled studies suggest that longer intensive treatments tend to have better outcomes than shorter, non-intensive treatments. The impact of psychoanalysis is evident not just in relation to symptoms, but as measured by patient's work performance and reduction in health-care costs.

Psychodynamic psychotherapy

In the UK, classic psychoanalysis requires the client to attend 3–5 sessions per week for several years (Fonagy, 2000) which for many people is far too expensive, as well as too time consuming.

In a modified form of analysis, therapist and client meet once or twice weekly for a limited period. There may be a 'contract' for a specified number of weeks as opposed to the open-ended arrangement of classic analysis. For example, Malan (1976) uses *brief focal therapy* (one session per week for about 30 weeks), in which the focus is on fairly specific psychological problems (such as a single conflict area or relationship in the client's current life). Although all the basic techniques of psychoanalysis may be used, there's considerably less emphasis on the client's past, and client and therapist usually sit in armchairs facing each other. This form of psychotherapy is practised by many clinical psychologists (as well as psychiatrists and social workers), who haven't received a full-blown psychoanalytic training (Fonagy, 1995; Fonagy & Higgitt, 1984). Fonagy (2000) cites evidence supporting the effectiveness of brief dynamic psychotherapy.

BEHAVIOURAL APPROACHES

Models of psychological disorder

According to the behavioural model, all behaviour, whether adaptive or maladaptive, is acquired by the same principles of classical and/or operant conditioning (see Chapter 11).

The medical model is completely rejected, including any distinction between 'symptoms' and underlying pathology. According to Eysenck (1960), if you 'get rid of the symptom... you have eliminated the neurosis'. But according to Freud, if treatment tackles only the symptoms and not the underlying conflict, new neurotic symptoms will replace those which are removed (*symptom substitution*).

However, this is increasingly being seen as an oversimplification and misunderstanding of what behaviour therapy involves. Wachtel (1989), for example, argues that in some ways all theories and therapies make assumptions about 'symptoms as manifestations of some underlying problem'. What distinguishes different approaches is the view taken of the *nature* of those underlying problems, and how much change is needed for the problem to be remedied. He calls for an integration between the two approaches which, in practice, is already happening.

Behavioural technology vs behavioural analysis

According to Mackay (1975), some behaviour therapists (e.g. Eysenck, Rachman, and Marks) try to discover which techniques are most effective with particular diagnostic groups. This *nomothetic* approach is called *behavioural technology*. Others (e.g. Yates and Meyer) believe that therapists should isolate the stimuli and consequences that are maintaining the inappropriate behaviour in each individual case, and that, accordingly, any treatment programme should be derived from such a 'behavioural analysis' (or 'functional analysis'). This *idiographic* approach is called *behavioural psychotherapy*.

Part of the functional analysis is an emphasis on current behaviour–environment contingencies, in contrast to the Freudian emphasis on past (particularly early childhood) events, and unconscious (and other internal) factors. Psychological problems are *behavioural* problems, which need to be *operationalised* (described in terms of observable behaviours) before we attempt to change them. According to Richards (2002), 'behavioural psychotherapy' is now the preferred term for describing all the techniques that have traditionally been called 'behaviour therapy' as well as those that are often discussed under the separate heading (as in this chapter) of *cognitive behaviour therapy* (CBT). For many clinical psychologists, the theoretical models of abnormality that behavioural techniques are derived from are less important than the fact that they are *evidence-based:*

> ... Behavioural psychotherapy has ... developed via a potential mix of evidence from both science and clinical trials ... for many clinicians, the theories of learning most often associated with behavioural psychotherapy matter far less than evidence-based technical eclecticism – i.e. what works for patients (Richards, 2002)

Classical conditioning, phobias and preparedness

ASK YOURSELF...

- How, according to classical conditioning, do phobias arise? (See Chapter 11, pages 174–175.)
- What are the limitations of this explanation?

According to Eysenck & Rachman (1965), the case of Little Albert exemplifies how all phobias are acquired (i.e. through classical conditioning):

> Any neutral stimulus, simple or complex, that happens to make an impact on an individual at about the time a fear reaction is evoked, acquires the ability to evoke fear subsequently... there will be generalisation of fear reactions to stimuli resembling the conditioned stimulus ... (Wolpe & Rachman, 1960)

One of the problems with this explanation is that some phobias are easier to induce in the laboratory than others (in participants who don't already have them), and it's well known that certain naturally occurring phobias are more common than others. These findings are consistent with Seligman's (1970) concept of *preparedness*.

Even more difficult for the classical conditioning model to explain is the *persistence* of naturally occurring phobias (that is, their failure to extinguish).

ASK YOURSELF...

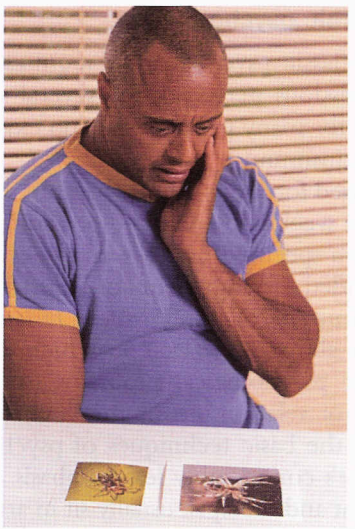
- How can *operant conditioning* help to explain the persistence of phobias? (See Chapter 44, page 778.)

Mowrer's (1960) 'two-process' theory has been extremely influential in behavioural psychotherapy, much of which is aimed at helping clients to modify the reinforcers ('maintenance factors') that keep their problem behaviours going. People are helped to break the cycle of fear and *avoidance* (Richards, 2002: see below).

The persistence of neurotic behaviour may also be accounted for in terms of what Freud (1926) called *secondary gain*. This refers to the attention and sympathy the neurotic receives from other people, which (unintentionally) positively reinforces it.

Behaviour therapy

Behaviour therapy (BT) refers to techniques based (primarily) on *classical conditioning,* developed by psychologists such as Eysenck and Wolpe. Wolpe (1958) defined behaviour therapy as 'the use of experimentally established principles of learning for the purpose of changing unadaptive behaviour'.



Systematic desensitisation

The case of Little Peter (see Chapter 11) represents the earliest example of any kind of behavioural treatment, and the methods used to remove his phobia of animals were later called *systematic desensitisation* (SD) by Wolpe (1958). It represents a form of *counter-conditioning,* and the key principle in SD is that of *reciprocal inhibition,* according to which:

> ... if a response inhibitory of anxiety can be made to occur in the presence of anxiety-evoking stimuli it will weaken the bond between these stimuli and the anxiety ... (Wolpe, 1969)

Joseph Wolpe (1915–1997)

Behaviour therapy with a spider phobic

In other words, it's impossible for someone to experience two opposite emotions (e.g. anxiety and relaxation) at the same time. Accordingly, a patient with a phobia is first taught to relax through deep muscle relaxation, in which different muscle groups are alternately relaxed and tensed (alternatively, hypnosis or tranquillisers might be used). So, relaxation and fear of the object or situation 'cancel each other out' (this is the '*desensitisation*' part of the procedure).

The '*systematic*' part of the procedure involves a graded series of contacts with the phobic object (usually by imagining it), based on a *hierarchy* of possible forms of contact from the least to the most frightening. Starting with the *least* frightening form of contact, the patient, while relaxing, imagines the object (e.g. the word 'spider' on a printed page) until this can be managed without feeling any anxiety at all. Then, and only then, the next most feared contact will be dealt with, in the same way, until the *most* frightening contact can be imagined with no anxiety (e.g. a large, hairy spider running all over your body).

Wolpe used imagination, because some of his patients' fears were so abstract (e.g. fear of criticism or failure) that it was impractical to confront them using real-life situations. He also believed that the ability to tolerate stressful imagery is generally followed by a reduction in anxiety in related real-life situations. Between sessions, patients are usually instructed to put themselves in progressively more frightening real-life situations. These 'homework assignments' help to move their adjustment from imagination to reality (Davison & Neale, 1994).

An evaluation of SD

- Rachman & Wilson (1980) and McGlynn *et al.* (1981) believe that SD is definitely effective, although it's most effective for the treatment of specific phobias (e.g. animal phobias) as opposed to, say, agoraphobia (see Chapter 44), and for patients capable of learning relaxation skills and with sufficiently vivid imaginations to be able to conjure up the sources of their fear.

- A limitation of SD is that some patients may have difficulty transferring from the imaginary stimulus to real-life situations.
- There's some debate as to whether either relaxation or the use of a hierarchy of contact situations is actually necessary at all. According to Wilson & Davison (1971), for example, relaxation might be merely a useful way of encouraging a frightened person to confront what they're afraid of, which would otherwise be avoided.
- According to Marks (1973), SD works not because of the inhibiting effect of relaxation on anxiety (reciprocal inhibition), but because of the *exposure* to the feared situation; this seems to represent the generally accepted view among psychologists. Exposure is especially effective if it allows the person to disprove his or her predictions that something awful will happen if they come into contact with the feared object or situation, and graded exposure helps to build up the person's confidence to be able to cope with the exposure (Williams & Hargreaves, 1995).
- According to Richards (2002), graded exposure *in vivo* (that is, confronting real-life animals or situations) is the 'singularly most effective psychotherapeutic technique of modern times'.

Implosion (implosive therapy) and flooding

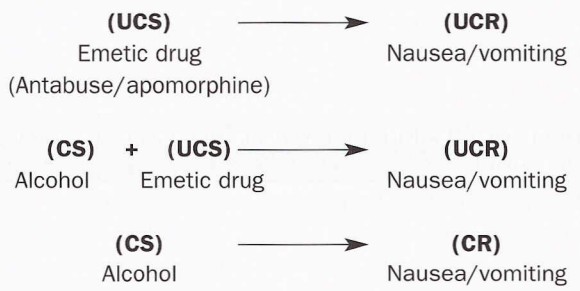
The essence of *implosion* is to expose the patient to what, in SD, would be at the top of the hierarchy. Instead of gradual exposure accompanied by relaxation, the patient is 'thrown in at the deep end' right from the start. This is done by getting the patient to imagine their most terrifying form of contact (the big, hairy spider let loose, again) with vivid verbal descriptions by the therapist (*stimulus augmentation*) to supplement the patient's vivid imagery. How is it meant to work?

- The patient's anxiety is maintained at such a high level that eventually some process of *exhaustion* or *stimulus satiation* takes place – the anxiety level can only go down!
- *Extinction* occurs by preventing the patient from making the usual escape or avoidance response (Mowrer, 1960). Implosion (and flooding), therefore, represents a form of 'forced reality testing' (Yates, 1970).

Flooding is exposure that takes place *in vivo* (e.g. with an actual spider). Marks *et al.* (1971, cited in Marks, 1981a) compared SD with flooding, and found flooding to be superior. Gelder *et al.* (1973) compared SD with implosion and found no difference.

ASK YOURSELF...

- What conclusions can you draw from these findings?



These findings suggest that *in vivo* exposure is what's crucial, and several researchers consider flooding to be more effective than implosion. Emmelkamp & Wessels (1975) and Marks (1981b) used flooding with agoraphobics very successfully, and other studies have reported continued improvement for up to 9 years after treatment without the appearance of 'substitute' problems. Wolpe (1973) forced an adolescent girl with a fear of cars into the back of a car and drove her around continuously for four hours. Her fear reached hysterical heights but then receded and, by the end of the journey, had completely disappeared. Marks (1981a), in a review of flooding studies, found it to be the most universally effective of all the techniques used to treat phobias.

ASK YOURSELF...

- Do you think that flooding is an ethically acceptable method of treating phobias?

Aversion therapy

In *aversion therapy,* some undesirable response to a particular stimulus is removed by associating the stimulus with another, aversive, stimulus. For example, alcohol is paired with an emetic drug (which induces severe nausea and vomiting), so that nausea and vomiting become a conditioned response to alcohol.

Malcolm McDowell in a scene from *Clockwork Orange*. His eyes are clamped open, forcing him to watch a film portraying acts of violence and sadism, as part of aversion therapy. He'd earlier been given an emetic drug, so that extreme nausea and violence will become associated

Patients would, typically, be given warm saline solution containing the emetic drug. Immediately before the vomiting begins, they're given a four-ounce glass of whisky which they're required to smell, taste and swill around in the mouth before swallowing. (If vomiting hasn't occurred, another straight whisky is given and, to prolong nausea, a glass of beer containing emetic.) Subsequent treatments involve larger doses of injected emetic, or increases in the length of treatment time, or a widening range of hard liquors (Kleinmuntz, 1980). Between trials, the patient may sip soft drinks to prevent generalisation to all drinking behaviour and to promote the use of alcohol substitutes. Meyer & Chesser (1970) found that about half their alcoholic patients abstained for at least one year following treatment, and that aversion therapy is better than no treatment at all.

More controversially, aversion therapy has been used with homosexuals, fetishists, male transvestites, and sado-masochists. Marks *et al.* (1970) reported desired changes for up to two years after treatment. In a typical treatment, slides of nude males are presented to male homosexuals, and then quickly followed by electric shocks. The conditioned response to the slides is intended to generalise to homosexual fantasies and activities outside the treatment sessions. More recently, attempts have been made to replace homosexual responses with heterosexual ones, by showing slides of naked females: any sexual response will terminate the shock.

CRITICAL DISCUSSION 45.3 Aversion therapy as a form of heterosexism

- Many psychologists have argued that the social pressures on homosexuals to become 'straight' make it difficult to believe that the small minority of people who consult therapists for help in changing sexual preference are acting from choice (Davison & Neale, 1994).
- The very fact that *change-of-orientation* treatments exist can be seen as condoning *heterosexism*. Clinicians work to develop procedures and study their effects only if they're concerned about the problem which their techniques are intended to remedy. The therapeutic literature contains relatively little material on helping homosexuals develop as individuals without this involving a change of sexual orientation. This contrasts with the many books and articles on how best to discourage homosexual behaviour and replace it by heterosexuality.
- One very radical proposal is that therapists shouldn't help homosexuals become straight, even when such treatment is requested. But this, in turn, raises basic questions about limiting the options available to clients and, in refusing such treatment, aren't therapists making value judgements, just as they are when they agree to it? Isn't it the professional responsibility of therapists to meet the needs expressed by their clients? However, a client's request for a certain kind of treatment has never been sufficient justification for providing it (Davison & Neale, 1994).
- In fact, there's been a dramatic reduction in the use of aversion therapy with homosexuals since the mid-1970s.

ASK YOURSELF...

- What to do you think about the issues raised in Critical Discussion 45.3? (See Chapter 48 for a discussion of more general ethical issues relating to therapies.)

Covert sensitisation

Covert sensitisation (Cautela, 1967) is a variant of aversion therapy, which also includes elements of SD. 'Covert' refers to the fact that both the behaviour to be removed and the aversive stimulus to be associated with it are *imagined*. The patient has to visualise the events leading up to the initiation of the undesirable behaviour: just as this happens, s/he has to imagine nausea or some other aversive sensation.

'Sensitisation' is achieved by associating the undesirable act with an exceedingly disagreeable consequence (Kleinmuntz, 1980). The patient may also be instructed to rehearse an alternative 'relief' scene in which, for example, the decision not to drink is accompanied by pleasurable sensations. This is generally preferred to aversion therapy on humanitarian grounds, but is no more effective than aversion therapy (Gelder *et al.*, 1989).

Behaviour modification

Behaviour modification refers to techniques based on *operant conditioning*, developed by psychologists such as Ayllon and Azrin to build up appropriate behaviour (where it didn't previously exist), or to increase the frequency of certain responses and decrease the frequency of others.

According to Baddeley (1990), most behavioural programmes follow a broadly similar pattern involving a series of steps.

- **Step 1** Specify the behaviour to be changed. It's important to choose small, measurable, achievable goals.
- **Step 2** The goal should be stated as specifically as possible.
- **Step 3** A *baseline rate* should be measured over a period of several days, that is, how the person 'normally' behaves with respect to the selected behaviour. This may involve detailed observation, which can suggest hypotheses as to what's maintaining that behaviour.
- **Step 4** Decide on a *strategy*. For example, *selectively reinforce* non-yelling behaviour (through attention) and ensure that yelling behaviour is ignored.
- **Step 5** *Plan treatment*. It's essential that everyone coming into contact with the patient behaves in accordance with the chosen strategy.

A design that is commonly used to check the effectiveness of treatment is the *AB–AB design,* where A is the baseline condition and B is the experimental treatment. So, if treatment is working, the level of yelling should be reduced during the initial B-phase (compared with the initial A-phase), and should increase again when treatment is stopped (the second A-phase). When treatment is reintroduced (second B-phase), yelling should once more reduce.

- **Step 6** *Begin treatment.*
- **Step 7** *Monitor progress.*
- **Step 8** *Change* the programme if necessary.

Operant conditioning with special groups

Even under optimum conditions, autistic children never achieve the creative use of language and broad range of social skills of normal children (Thomas, 1985: see Chapter 40). However, Lovaas (1977) believes that many therapeutic gains can be retained at home (and even some modest improvements shown) if parents have been trained in the *shaping techniques* such as those described in Key Study 45.2.

ASK YOURSELF...

- What do you understand by the term 'shaping'?
- What's a more technical terms for shaping?
- How do you think shaping might be used to help autistic children develop language?

KEY STUDY 45.2 Shaping speech in autistic children (Lovaas *et al.*, 1967)

Lovaas *et al.* pioneered operant conditioning with autistic children who normally had little or no normal speech. They used a *shaping* technique.

- Verbal approval was paired with a piece of food whenever the child made eye contact, or merely attended to the therapist's speech or behaviour (which is also unusual for autistic children). This reinforces attention and associates a positive social gesture with food, so that verbal approval eventually becomes a conditioned reinforcer.
- The child was reinforced with food and praise whenever it made any kind of speech sound, or even tried to imitate the therapist's actions.
- Once this occurred without prompting, the therapist gradually withheld reinforcement until the child successfully imitated complete actions or uttered particular vowel or consonant sounds, then syllables, then words and, finally, combinations of words.

Sometimes, hundreds or even thousands of reinforcements were necessary before the child began to label objects appropriately or imitate simple phrases. Even when children have received extensive training, they're likely to regress if returned to a non-supportive institutional setting.

There are many striking examples of successful modification programmes with the mentally retarded, both adults and children. In one large-scale study, Matson *et al.* (1980) reported substantial improvements in the eating behaviour of profoundly impaired adults. They used peer and therapist modelling (see below), social reinforcement, verbal prompts to shape eating, the use of utensils, table manners, and so on. Reinforcers included going to meals early, and having one's own table-mat. There was a significant improvement in the treated group even four months after the end of treatment, compared with an untreated control group.

Azrin & Foxx (1971) and Foxx & Azrin (1973) produced a toilet-training 'package' in which:

- the client is taken to the toilet every half hour and given extra fluids, sweets, biscuits, praise and attention when it's used successfully
- the client is strapped into a chair for half an hour, away from other people, if they have an accident; this *isn't* a punishment procedure, but *'time out',* that is, a time away from positive reinforcement.

As with speech training in autistic children, there are problems of generalising from hospital-based improvement to the home situation. But if parents continue the programme at home, there can be short- and long-term benefits.

A form of behaviour often displayed by autistic and mentally retarded individuals is *self-mutilation* by biting, scratching, head banging, and so on, all of which can be life-threatening. This has been treated successfully by using operant techniques (e.g. Bull & LaVecchio, 1978).

The token economy

The *token economy* (TE) is based on the principle of secondary reinforcement. Tokens (secondary or conditioned reinforcers) are given for socially desirable/acceptable behaviours as they occur, and can then be exchanged ('cashed in') later on for certain 'primary' reinforcers.

The TE was introduced by Ayllon & Azrin (1968), who set aside an entire ward of a psychiatric hospital for a series of experiments in which reinforcements were provided for activities such as face-washing, teeth-brushing, dressing properly, and making beds, and withheld for withdrawn or bizarre behaviour. The participants were 44 female chronic schizophrenic patients, with an average 16 years of hospitalisation. Some screamed for long periods, some were mute, many were incontinent, and a few were assaultive. Most no longer ate with cutlery, and some buried their faces in the food.

A baseline measure was made of how often socially desirable behaviours normally occurred. They were then systematically reinforced every time the desired behaviours occurred with *plastic tokens* that could later be

exchanged for special privileges (e.g. listening to records, going to the cinema, renting a private room, extra visits to the canteen). The entire life of each patient was, as far as possible, controlled by this regime. Results showed that the patients significantly increased the frequency of the desired behaviours when they were reinforced.

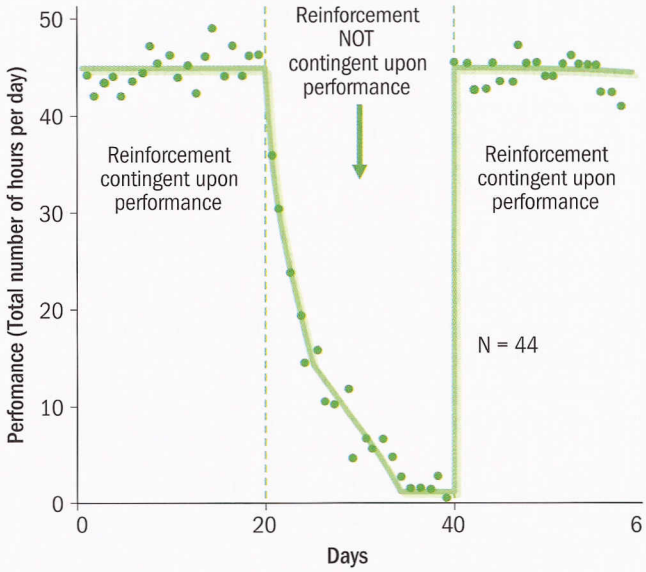


Figure 45.3 The effects of a token economy on the performance of 44 female hospitalised schizophrenics (from Ayllon & Azrin, 1968)

If the introduction of chlorpromazine and other antipsychotic drugs in the 1950s marked a revolution in psychiatry, the introduction of TE programmes during the 1960s was, in its way, equally revolutionary. This was partly because it drew attention to the ways in which nursing (and other) staff were inadvertently maintaining the psychotic, 'mad' behaviour of many chronic schizophrenics by giving them attention, thus reinforcing unwanted behaviour.

Evaluating the TE

Two main advantages of the TE are:

- tokens can be given *immediately* after some desirable behaviour occurs, thereby 'bridging' very long delays between the target response and the primary reinforcer; this is especially important when it's impractical or impossible to deliver the primary reinforcer immediately following the behaviour
- tokens make it easier to give consistent and effective reinforcers when dealing with a group of individuals.

According to Davison *et al.* (2004):

> ... These experiments have demonstrated how even markedly regressed adult hospital patients can be significantly affected by systematic manipulation of reinforcement contingencies ...

Since the 1960s, hundreds of carefully controlled experiments have shown that various psychiatric patient behaviours can be brought under control by manipulating reward and punishment contingencies. According to Holmes (1994), one of the most impressive tests of the effectiveness of the TE is a study by Paul & Lentz (1977).

KEY STUDY 45.3 A comparison of TE, milieu therapy and custodial care (Paul & Lentz, 1977)

Eighty-four chronic psychiatric patients, matched for age, gender, socio-economic status, symptoms, and length of hospitalisation, were randomly assigned to one of three treatment conditions.

Social learning/token economy

Acceptable behaviour was reinforced by giving the patients tokens, but learning took place specifically through modelling, shaping, prompting, and instructions. Inappropriate behaviour wasn't reinforced. This regime embraced all aspects of the patients' lives. Like money, the tokens were a necessity – they bought meals. They could also be used to rent better sleeping quarters (e.g. a single room cost 22 tokens), obtain passes to leave the hospital, buy recreation time (e.g. TV, piano), and various luxuries/privileges (e.g. staying up later). These all had to be 'earned'.

Milieu therapy

The entire hospital became a 'therapeutic community' (Jones, 1953), with all its ongoing activities and personnel a part of the treatment programme. Social interaction and group activities were encouraged, so that through group pressure, patients were directed towards normal functioning. They were treated as responsible human beings, and expected to participate in their own readjustment (as well as that of fellow patients), including participation in decision making about the running of the ward. Staff impressed on them their positive expectations and praised them for doing well.

Custodial care (routine hospital management)

This included the use of antipsychotic drugs. Patients were alone for 95 per cent of their waking hours, with only occasional recreational, occupational, individual and group therapies.

The study lasted for four and a half years, with an 18-month follow-up. Throughout the entire six-year period, patients were assessed at regular six-monthly intervals, using structured interviews and behavioural observation. The objectives of both the TE and milieu therapy were to teach self-care, housekeeping, communication and vocational skills, to reduce symptomatic behaviour, and to release patients into the community.

Both social learning/TE and milieu therapy reduced some symptoms (such as bizarre motor behaviours). They were also both successful in increasing interpersonal, vocational, housekeeping and self-care skills (TE being the more successful). But both were equally unsuccessful in reducing cognitive distortions (delusions, hallucinations, and incoherent speech) and hostile behaviour.

Over 10 per cent of patients in the TE and 7 per cent of those in milieu therapy were able to leave the hospital to live independently (e.g. in halfway houses), compared with none in custodial care. Those from the TE did significantly better at staying there. However, most of those who lived independently continued to manifest many signs of mental disorder, and failed to gain employment or participate in 'normal' social activities. The numbers of patients remaining on antipsychotic drugs dropped dramatically for those in both the milieu and TE groups.

According to Davison *et al.* (2004), considering how poorly these patients had been functioning before the study began, the results are extraordinary. However, since modelling and other social learning techniques were combined with the TE, the results shouldn't be accepted as demonstrating the effectiveness of the TE as such. Nevertheless:

> ... The outcome ... is not to be underestimated: chronic mental patients, those typically shut away on back wards and forgotten by society, can be resocialized and taught self-care. They can learn to behave normally enough to be discharged from mental institutions. This is a major achievement in mental health care ... (Davison *et al.*, 2004)

However, there's been very little increase in the use of TEs, despite continuing evidence of their effectiveness (Paul & Menditto, 1992).

Box 45.7 Some problems with TEs

- The control of behaviours has to be transferred from tokens to social reinforcers, both within and, ultimately, outside the hospital. The former is normally achieved by gradually 'weaning' patients off the tokens, and the latter by transferring patients to halfway houses and other community live-in arrangements. But there tends to be a high re-hospitalisation rate for such patients.
- Tokens may work by encouraging staff to observe behaviour systematically – not because the tokens act as reinforcers of the patient's behaviour (Gelder *et al.*, 1989). Indeed, Burgio *et al.* (1983) found that selectively reinforcing *staff* for verbal interaction with residents produced a reliable improvement in the residents' behaviour. As with other successful behavioural interventions, the reason for the effectiveness of TE programmes may be quite unrelated to learning theory principles (Fonagy & Higgitt, 1984). This relates to *process research* (see text below).
- *Ethical problems* arise, because it's often necessary to deprive patients of some amenity before it can be earned with tokens. If this amenity is something that the patient should have by right (e.g. food), there's clearly an ethical difficulty. With some amenities (e.g. watching TV), it's difficult to decide whether they're a right or a privilege (Gelder *et al.*, 1989).
- Ayllon and Azrin adopted the policy of giving visitors conducted tours, with the clients as guides. In some TEs, clients have the option of leaving the programme without penalty, and suggesting or negotiating changes in the contingencies used. Another precaution is to inform clients clearly of their legal and moral rights, and to instruct clients and staff to report any infringements of those rights. According to Martin & Pear (1992), the ethics of a TE will ultimately be judged on the basis of how effectively and humanely the transfer to the natural environment is carried out.
- Baddeley (1990) argues that when used in an educational setting (e.g. in a home for emotionally disturbed children), a TE can instil a highly mercenary approach to learning (TEs lead to *token learning*). For example, children may only read or indulge in any educational activity if directly rewarded for it. This may be effective within the confines of the TE itself, but will be inappropriate outside, where learning operates on a more indirect, long term, and less immediate reward system.

Custodial care: non-therapeutic, routine hospital management

COGNITIVE–BEHAVIOUR THERAPY

Model of psychological disorder

According to Mahoney (1974) and Meichenbaum (1977), many (if not most) clinical problems are best described as disorders of thought and feeling. Since behaviour is to a large extent controlled by the way we think, the most logical and effective way of trying to change maladaptive behaviour is to change the maladaptive thinking which lies behind it. Beck (1993) defines *cognitive–behaviour therapy* (CBT) as:

... the application of the cognitive model of a particular disorder with the use of a variety of techniques designed to modify the dysfunctional beliefs and faulty information processing characteristic of each disorder ...

CBT is derived from various sources, including behaviour therapy and psychoanalysis, which define and operationalise cognition in different ways. However, the attempt to change cognition (*cognitive restructuring*) is always a means to an end, that end being 'lasting changes in target emotions and behaviour' (Wessler, 1986).

Rational emotive therapy (RET) (Ellis, 1962, 1973)

Ellis argues that *irrational thoughts* are the main cause of all types of emotional distress and behaviour disorders. Irrational thinking leads to a self-defeating internal dialogue of negative self-statements, and these are seen as 'covert' behaviours, subject to the same principles of learning as overt behaviour. Phobias, for example, are linked to *catastrophising self-statements* and, as with other disorders, the aim of therapy is to replace these irrational, unreasonable beliefs and ideas with more reasonable and realistic ones.

In its simplest form, patients are told to look on the bright side, stop worrying, pull themselves together, and so on. As Walker (1984) observes, 'rational' shouldn't be taken too literally, as sometimes counterproductive thoughts and beliefs may be replaced by more positive and helpful but equally irrational ones. For instance, it's not necessarily more rational to be an optimist than a pessimist, but it's usually more productive and should be encouraged in depressed patients.

Ellis (1962) identified 11 basic irrational beliefs or ideas which tend to be emotionally self-defeating, and which are commonly associated with psychological problems. These include, 'I must be loved and accepted by absolutely everybody', and 'I must be excellent in all possible respects and never make mistakes – otherwise I'm worthless'. In RET, patients are challenged to prove that they're worthless because they make mistakes, or to say exactly how making mistakes makes one a worthless person. Patients may be explicitly directed to practise certain positive/optimistic statements, and are generally urged to 'look for the "musts" when they experience inappropriate emotions' (Wessler, 1986).

Self-instructional training (SIT) (Meichenbaum, 1977)

According to Meichenbaum, neurotic behaviour is due, at least partly, to *faulty internal dialogues* (internal speech), in which the patient is failing to self-instruct successfully. The underlying rationale for SIT is a study by Meichenbaum & Goodman (1971). Impulsive and hyperactive children were trained to administer self-instructions for tasks on which they'd previously made frequent errors, first by talking aloud, then covertly, without talking, but still moving their lips and, finally, by talking covertly without any lip movements. This 'silent speech' is the essence of verbal thought (see Chapter 34).

Patients are made aware of the maladaptive nature of their self-statements, and are then helped to develop coping skills in the form of coping self-statements, relaxation, and plans for behaviour change. For example, a patient might write down a strategy for dealing with a particular social interaction (e.g. asking someone to dance at a club) and then role-play it with a continuous commentary of self-statements before actually doing it 'for real'.

Wolpe (1978) argues that these techniques aren't very useful in cases of severe anxiety, because many strong neurotic fears are triggered by objects and situations which the patient knows are harmless – this is why phobias are irrational! So, Wolpe has used a technique called *thought stopping* (mainly with OCD patients), in which the patient is told to dwell on their obsessive thoughts and, while this is happening, the therapist shouts 'Stop!'. The patient then repeats the command out loud, and eventually repeats it subvocally (in thought only). (Covert sensitisation is a form of self-instruction or self-training: see above.)

Treatment of 'automatic thoughts' (Beck, 1963, 1967, 1987)

Beck's central idea is that depressed individuals feel as they do because their thinking is dominated by *negative schemas*. This is a tendency to see the world negatively, which is triggered whenever the person encounters new conditions that in some way resemble the conditions in which the schemas were originally learned (usually in childhood and adolescence). These negative schemas fuel and are fuelled by certain cognitive biases, which cause the person to mis-perceive reality. So:

(a) an *ineptness schema* can make depressed people expect to fail most of the time
(b) a *self-blame schema* makes them feel responsible for all misfortunes, and
(c) a *negative self-evaluation schema* constantly reminds them of their worthlessness. The main specific cognitive biases are described in Box 45.8.

Box 45.8 The main cognitive biases in Beck's theory of depression

- **Arbitrary inference:** a conclusion drawn in the absence of sufficient evidence – or any evidence at all. For example, a man concludes that he's worthless because it's raining the day he's hosting an outdoor party.
- **Selective abstraction:** a conclusion drawn on the basis of just one of many elements in a situation. For example, a worker feels worthless when a product doesn't work, even though she's only one of several people who contributed to making it.

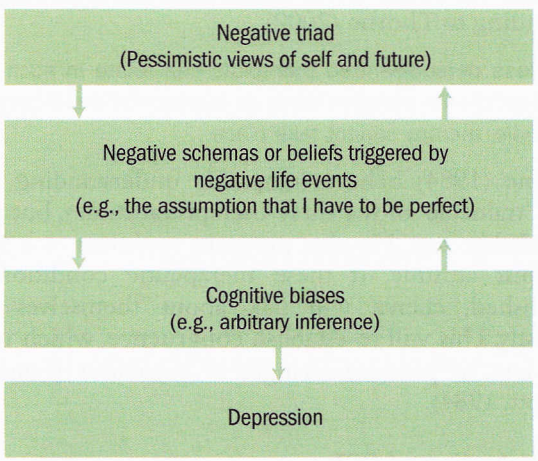
- **Overgeneralisation:** an overall sweeping conclusion drawn on the basis of a single, perhaps trivial, event. For example, a student regards his poor performance in a single class on one particular day as final proof of his worthlessness and stupidity.
- **Magnification and minimisation:** exaggerations in evaluating performance. For example, a man believes he's completely ruined his car (*magnification*) when he sees a small scratch on the rear bumper. A woman believes herself to be worthless (*minimisation*) despite a succession of praiseworthy achievements.

(Based on Davison & Neale, 2001)

Negative schemas, together with cognitive biases or distortions, maintain the *negative triad*. This refers to negative thoughts about the self, the world and the future.

The source of such negative thoughts are logical errors based on faulty 'data' and, once negative thinking has been identified, it can be replaced by collecting evidence against it. Accordingly, Beck sees the client as a colleague of the therapist who researches verifiable reality (Wessler, 1986).

For example, if a client expresses the negative thought, 'I'm a poor father because my children aren't better disciplined', Beck would take the second part of the statement and seek factual evidence about its truth. He'd also focus on the evaluative conclusion that one is a poor father because one's children sometimes misbehave. In these and other ways, clients are trained to distance themselves from things, to be more objective, to distinguish fact from fiction, and fact from evaluation, to see things in proportion, and not to see things in such extreme terms. Beck's cognitive therapy is less confrontational than RET.



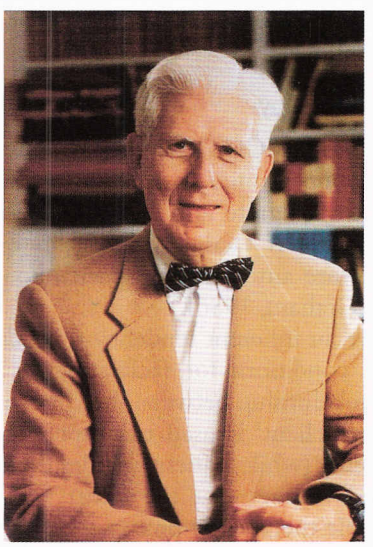


Figure 45.4 The interrelationships between different kinds of cognitions in Beck's theory of depression

An evaluation of Beck's approach

- It's generally agreed that Beck's has been the most influential of the cognitive models of depression (that is, the view that depression is caused by how people *think*) (Champion, 2000), although it's also been criticised for underemphasising social factors (Champion & Power, 1995).
- Freud saw people as victims of their passions. The id is the dominant part of the personality, and the ego is able to exert little control over our feelings. But in Beck's theory, the cause–effect relationship is *reversed*. Our emotional reactions are essentially a function of how we *construe* the world (interpret and predict it). Depressed people see themselves as victims, and Beck sees them as victims of their own illogical self-judgements.
- The evidence initially came from Beck's clinical observations (Beck, 1967). Further support comes from various sources, including self-report questionnaires, and laboratory studies of memory and other cognitive processes (Davison & Neale, 2001).
- Perhaps the greatest challenge facing any cognitive theory of depression is to show that depressed people's thoughts are the *cause* of their depression rather than the effect. Many experimental studies have shown that a person's mood can be influenced by how s/he construes events. But manipulating people's affect (mood or feeling) has also been shown to change their thinking. Beck (and others) have found that depression and certain kinds of thinking are *correlated*. But a specific causal relationship cannot be determined from such data (as with all correlations). Probably, the relationship works *both* ways. In recent years, Beck himself has come to this more *bidirectional* position. There's certainly no unequivocal support for the claim that negative thinking causes depression (Davison & Neale, 2001).

Aaron T. Beck (born 1921)

◎ Beck (1993) has reviewed the evidence concerning the effectiveness of his form of CBT in the treatment not just of unipolar depression (for which it was originally designed), but also generalised anxiety disorder, panic disorder and eating disorders. These *outcome studies* show very clearly that CBT is highly effective (see below, pages 829–832). CBT is also being used in the treatment of drug abuse, bipolar disorder, patients with cancer, HIV, OCD, PTSD and schizophrenia, and it's also being applied in group and family therapy settings. Beck (1993) believes that:

> The very broad application of the theory and strategies bolsters the claim of cognitive therapy as a robust system of psychotherapy ...

CLIENT-CENTRED THERAPY (CCT) (ROGERS, 1959)

Model of psychological disorder

As we saw when discussing Rogers' self theory in Chapter 42, when a person is aware of a lack of congruence between their experience and self-concept, threat, anxiety or depression is experienced. Because of our need for positive regard, we may behave in ways which are discordant with the values of our self, and feeling threatened, anxious, or depressed is the price we pay. Denial and distortion are used as defences against these unpleasant feelings, and as a result our self-concept becomes increasingly incongruent with reality. This, in turn, increases anxiety and makes the need for defences all the greater, creating a vicious circle.

Threat, anxiety, or depression may interfere with the person's life in a less serious (neurotic) way, or it may be so great as to defy denial and distortion, leading to the disintegration of personality (psychosis). However, Rogers regards individuals as unique, and human personality is so complex that no diagnostic labelling of persons can ever be fully justified. Indeed, Rogers rejected all diagnostic labelling.

The aims of therapy

Client-centred therapy (CCT) is a process whereby individuals have the opportunity to reorganise their subjective world, so as to integrate and actualise the self. The key process, therefore, is facilitation of the experience of becoming a more autonomous, spontaneous, and confident person (Graham, 1986).

People have an inherent tendency towards *self-actualisation,* but the conditions for facilitating its development reside in the relationship between the client and the therapist. The word 'client' is used to emphasise the person's self-responsibility (while 'patient' implies the opposite), and 'client-centred' implies that the client is encouraged to direct the whole therapeutic process – any changes which occur during therapy are brought about by the client.

The therapeutic process

The therapist's main task is to create a therapeutic atmosphere in which clients can become fully integrated again. This can be achieved only if clients *reduce their conditions of worth,* and *increase their unconditional positive self-regard.* The therapist's job is to create a situation in which clients can change themselves, and this is aided by an emotionally warm, accepting, understanding, and non-evaluative relationship in which the person is free from threat and has the freedom to be 'the self that he really is' (Graham, 1986).

There are three particularly significant qualities to the relationship, or therapist attitudes, which must be effectively communicated to the client.

Box 45.9 The three therapist attitudes central to CCT

Genuineness (authenticity or congruence): The therapist must show him/herself to be a real person, with feelings which should be expressed where appropriate. The client needs to feel that the therapist is emotionally involved, and not hiding behind a facade of professional impersonality: the therapist must be 'transparent'. This is the most important of the three qualities or attitudes.

Unconditional positive regard: The therapist must show complete acceptance of, and regard for, the client as a separate person in his/her own right. The therapist must deeply and genuinely care for clients as they are now, in a non-judgemental way.

Empathic understanding: The therapist must try to enter the client's inner world through genuine, attentive listening, which involves intense concentration. This may involve restating what the client says as a way of trying to clarify its emotional significance (rather than its verbal content). This requires the therapist to be sensitive to what's currently going on in the client's mind, and to meanings just below the level of awareness.

According to Thorne (2002):

> ... unless person-centred therapists can relate in such a way that their clients perceive them as trustworthy and dependable *as people,* therapy cannot take place ...

Thorne (1984) believes empathic understanding is the most 'trainable' of the three therapist attitudes, but is also remarkably rare. He also proposes *tenderness* as a fourth therapist attitude. If these therapeutic conditions are established, clients will talk about themselves more honestly. This will re-establish congruence, which will be sufficient to produce changes in behaviour (Fonagy & Higgitt, 1984).

An evaluation of CCT

◎ Unlike most other humanistic therapists, Rogers has attempted to validate his therapy empirically (and has

encouraged others to do so). A form of assessment used by Rogers is the *Q-sort,* which comprises a number of cards with statements referring to the self (e.g. 'I am a domineering person'). The client is asked to arrange them in a series of ten piles, ranging from 'very characteristic of me' to 'not at all characteristic of me' (describing the *self-image*), and the process is repeated so as to describe the *ideal self* (see Chapter 33). The two Q-sorts are then correlated to determine the discrepancy between self-image and ideal self – the lower the correlations, the greater the discrepancy. The whole procedure is repeated at various intervals during the course of therapy.

- One way of assessing the importance of the three qualities or therapist attitudes is to train people to do so, and to give them transcripts or tape-recordings of therapy sessions which they then have to rate. Truax & Mitchell (1971) found that therapists who were rated high were much more likely to be associated with desirable changes in their clients, and low-rated therapists actually made their clients' conditions *worse.* But others have found that the therapist's personal characteristics are likely to be no more important than any specific techniques used.
- Thorne (2002) would totally dispute this last claim, arguing that the limitations of CCT are a reflection of the personal limitations of the approach. However, he also argues that CCT has been in danger of selling itself short, because of its traditional emphasis on the here and now, and also because of its heavy reliance on verbal interaction. Rogers' own daughter, Natalie, has pioneered *person-centred expressive therapy* (Rogers, 1993), which incorporates movement, art, music, pottery and creative writing, as well as other essentially non-verbal channels of expression (see Box 45.1).

AN EVALUATION OF THERAPY: IS IT EFFECTIVE?

This deceptively simple-sounding question really comprises two interrelated questions:

1. does it work? This is related to *outcome research.*
2. how does it work? This is related to *process research.*

Each question, in turn, comprises several other overlapping questions. *Outcome questions* include the following:

- is psychotherapy (in general) effective?
- is any one kind of psychotherapy more effective than another?
- what constitutes a satisfactory outcome?
- how should change be measured (and for how long after the end of treatment)?
- how much and what kind of change is necessary for a judgement of improvement to be made?

Process questions include the following:

- what are the necessary components of effective therapy?
- what are the mechanisms by which change is brought about (what are the 'active ingredients')?
- are different therapies effective because of the particular techniques and tools they use, or are there common factors that apply to all therapies?

Despite the close connection between them, researchers tend to focus on either outcome or process questions. Psychotherapy research began by concentrating on outcome, in the form of Eysenck's much-cited 1952 review article, in which he challenged what had up to that time been taken for granted about the effectiveness of psychoanalysis.

KEY STUDY 45.4 The effectiveness of psychotherapy (Eysenck, 1952)

- Eysenck reviewed five studies of the effectiveness of psychoanalysis, and 19 studies of the effectiveness of 'eclectic' (mixed) psychotherapy.
- He concluded that only 44 per cent of psychoanalytic patients and 64 per cent of those who received the 'mixed' therapy improved.
- However, since roughly 66 per cent of patients improve without any treatment (*spontaneous remission*), Eysenck concluded that psychoanalysis in particular, and psychotherapy in general, simply don't work – they achieve nothing which wouldn't have happened anyway without therapy!

Outcome research

According to Eysenck (1992), the *outcome problem* had never been properly addressed by clinical psychologists prior to his article, which showed *only* that the available evidence wasn't sufficient to prove that psychoanalysis (and psychotherapy in general) was instrumental in bringing about recovery. It *didn't* suggest that it was ineffective (which is how many others interpreted his conclusions). Nevertheless, if it can be shown that psychoanalysis does *no better* than placebo treatments (see below) or no treatment at all (which the 1952 article showed):

> ... then clearly the theory on which it is based was wrong. Similarly, if there were no positive effects of psychoanalysis as a therapy, then it would be completely unethical to apply this method to patients, to charge them money for such treatment, or to train therapists in these unsuccessful methods ... (Eysenck, 1992)

By 1960, Eysenck was arguing that behaviour therapy is the only kind of therapy worth rational consideration and he inspired an enormous amount of research on therapy outcomes (Oatley, 1984).

A re-assessment of Eysenck's conclusions

- If the many patients who drop out of psychoanalysis are excluded from the 44 per cent quoted by Eysenck (they cannot legitimately be counted as 'failures' or 'not cured'), the figure rises to 66 per cent.
- Bergin (1971) reviewed some of the studies included in Eysenck's review and concluded that, by choosing different criteria of 'improvement', the success rate of psychoanalysis could be raised to 83 per cent. He also cited studies which showed only a 30 per cent spontaneous remission rate.
- One of the two studies which Eysenck used to establish his spontaneous remission rate of 66 per cent was conducted by Landis (1938). Landis compared patients who'd received psychotherapy ('experimental group') with a control group who'd been hospitalised for 'neurosis' in state mental hospitals. Landis himself pointed out a number of differences between his psychotherapy group and the hospital patient controls, concluding that these differences

  all argue against the acceptance of [this] figure... as a truly satisfactory baseline ...

- Bergin & Lambert (1978) reviewed 17 studies of untreated 'neurotics' and found a median spontaneous remission rate of 43 per cent. They also found that the rate of spontaneous remission varies a great deal depending on the disorder: generalised anxiety and depression, for example, are much more likely to 'cure themselves' than phobias or OCD. Similarly, Rachman & Wilson (1980) argue that:

  ... the early assumption of uniformity of spontaneous remission rates among different disorders is increasingly difficult to defend.

- Garfield (1992) argues that both the quantity and quality of psychotherapy research have increased since the time of Eysenck's 1952 article, especially since the 1970s, but Eysenck doesn't refer to this in his 1992 article (see quote above).

Other outcome research

A review by Luborsky *et al.* (1975) concluded that all types of therapy are equally effective. Smith & Glass (1977) reviewed 400 studies of a wide variety of therapies (including psychodynamic, CCT, SD, and eclectic) and concluded that all were more effective than no treatment. For example, the 'average' client who'd received therapy scored more favourably on the outcome measures than 75 per cent of those in the untreated control groups.

Smith *et al.* (1980) extended the 1977 study to include 475 studies (an estimated 75 per cent of the published literature). Strict criteria for accepting a study included the comparison of a treated group (given a specified form of therapy) with a second group (drawn from the same population) that were either given no therapy, put on a waiting list, or given some alternative form of therapy. As with the 1977 results, the effectiveness of therapy was shown to be highly significant: the average client was better off than 80 per cent of the control groups on the outcome measures. Although different therapies had different kinds of effects, overall:

Different types of psychotherapy (verbal or behavioural, psychodynamic, client-centred, or systematic desensitisation) do not produce different types or degrees of benefit. (Smith *et al.*, 1980)

Box 45.10 Meta-analysis

- A distinctive feature of the Smith & Glass (1977) and Smith *et al.* (1980) studies is their use of *meta-analysis* (MA), a 'study of studies'. Lilienfeld (1995) defines MA as:

  ... a procedure for aggregating and averaging the results of a large number of studies. Unlike the 'voting' method, meta-analysis allows researchers to consider the magnitude of findings and yield an overall measure of effect size – that is, an index of the magnitude of the effects of a treatment ... averaged across all studies ...

- *Effect size* is essentially an indicator of the extent to which people who receive psychotherapy improve relative to those who don't: the greater the difference between these two groups, the greater the effect size. The 'voting method' (a term coined by Smith and Glass) simply involves adding up all the studies that support the effectiveness of psychotherapy and all those that don't – a result is counted as a 'hit' provided the difference between the two totals is statistically significant. But lumping together all the positive findings and all the negative findings obscures statistically significant results that are very large and those that are very small. As a result, it provides only a crude and often misleading summary of a body of literature (Lilienfeld, 1995). All outcome studies prior to Smith & Glass (1977) used the 'voting method'.
- Another advantage of MA is that it allows researchers to examine whether certain variables are correlated with effect size, such as how experienced the therapist is and the age of clients. In this way, they can determine not only the overall effectiveness of psychotherapy (*outcome research*), but also what factors, if any, influence its effectiveness (*process research*).

Some problems with outcome research

ASK YOURSELF...

- Can you think of any criticisms of the *categorical approach* to diagnosing mental disorders that would seriously undermine any outcome study? (See Chapter 43.)

- Outcome research in general presupposes that it's possible to distinguish reliably and validly between mental disorders; in other words, schizophrenia, depression, and so on, are objectively separate mental illnesses (as are physical diseases). We saw in Chapters 43 and 44 that this is a matter of debate and disagreement (especially between psychiatrists and psychologists).
- Related to this is the widespread use of DSM categories in outcome research, so that patients are treated essentially the same (they're *homogeneous*). This is a *nomothetic* approach, while in practice, therapy adopts a more *idiographic* approach – treatment is tailored to the particular needs and characteristics of particular patients.

CRITICAL DISCUSSION 45.4 Manual research vs actual clinical practice

- Outcome research uses therapist *manuals*. These are detailed guides on how to conduct a particular therapy, stipulating specific procedures to be followed at different stages of treatment. This has become the norm in outcome research.
- Specifying what therapists are to do via a manual in a controlled study (*randomised clinical trial*/RCT) allows someone reading a study to know what actually happened to patients in a given experimental condition.
- But do the results from manual-based studies generalise to the actual practice of psychotherapy outside the constraints of the RCT (Davison *et al.*, 2004)? For example, most therapists describe themselves as *eclectic* (i.e. they draw on different approaches and techniques). This suggests that controlled studies of *specific* techniques and treatments are limited in what they can tell us about the nature and outcomes of therapy *as actually practised* (Lambert & Bergin, 1994). If most practising therapists rarely behave strictly in line with a particular theoretical orientation, RCTs can tell us little about the effectiveness of psychotherapy available to patients who aren't participating in such studies (Davison *et al.*, 2004).
- As Marzillier (2004) puts it, the very procedures designed to improve the research distance it from the realities of clinical work.
- The use of manuals is also designed to minimise the influence of differences between different therapists. But even in RCTs there's great variability between therapists (Teyber & McClure, 2000), and, in general, therapist differences are *greater* than treatment differences (Beutler, 1997). In CCT, therapist qualities are paramount, but also more generally, we mustn't let the focus on treatment variables blind us to the importance of therapist empathy, sensitivity and ability to inspire trust (Davison *et al.*, 2004).

Process research

ASK YOURSELF...

- Based on the earlier discussion of specific treatment methods, try to formulate some questions relevant to process research (i.e. *how* the methods work).

- Do relaxation and graded exposure to the feared object/situation make SD an effective means of removing phobias?
- Are tokens an essential part of the TE, which successfully reduces the psychotic behaviour of schizophrenic patients?
- Are the three therapist attitudes necessary if clients are to develop positive self-regard and to achieve congruence?

These are all questions about *process*. According to Kazdin & Wilcoxin (1976), the crucial ingredients of therapy (whatever techniques are involved) are:

- the patient is influenced to expect success, and
- the patient's self-concept changes, whereby s/he comes to believe (through supervised practice) that the previously feared object or situation can be coped with.

The patient's expectations of success relate to the crucial and controversial issue of the *placebo effect*.

The placebo effect

As we saw when discussing antidepressant drugs (see Box 45.4, page 812), a *placebo* denotes an inactive/inert substance, designed to take account of the psychological (as opposed to pharmacological) influences on physiological change (such as the expectation of improvement). So, in drug trials, the placebo condition is the *control condition*.

However, in psychotherapy, the expectancy is part of the treatment (Mair, 1992). Is it possible to devise a placebo control in psychotherapy research which is inactive in a way that's equivalent to taking a sugar pill? Even non-placebo controls (such as delayed treatment or no treatment conditions) will produce expectations specific to that particular condition (e.g. disappointment and rejection respectively) (Barkham & Shapiro, 1992).

If client expectations of success are one of the main 'active ingredients' or components involved in psychotherapy, then if a placebo has the capacity to inspire client expectations, making psychotherapy–placebo comparisons may underestimate the actual effectiveness of psychotherapy (Lilienfeld, 1995). Indeed, according to Frank (1989), if therapy effects don't exceed those of placebos (a conclusion drawn by, for example, Prioleau *et al.*, 1983), this is because the placebo is psychotherapy:

> As a symbolic communication that combats demoralisation by inspiring the patient's hopes for relief, administration of a

> placebo is a form of psychotherapy. It is therefore not surprising that placebos can provide marked relief in patients who seek psychotherapy. (Mair, 1989, quoted in Mair, 1992)

The role of non-specific factors

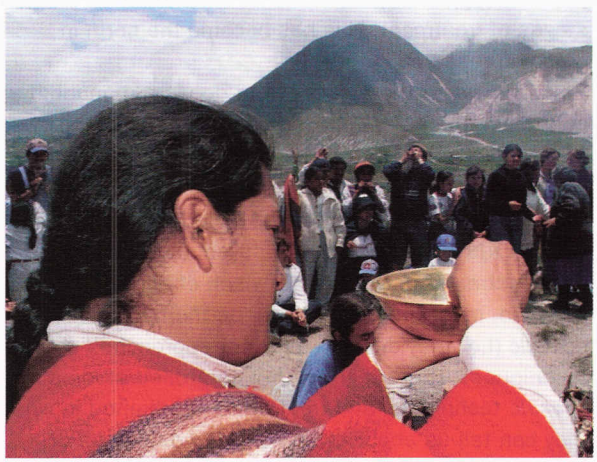
Cordray & Bootzin (1983) argue that one of the major ingredients involved in psychotherapy's effectiveness is the *non-specific factors* shared by most, or even all, therapies. The main proponent of this view is Frank (1973), who argues that psychotherapy has much in common with faith healing and other similar techniques. Far from being a derogatory comparison, Frank believes that the success of psychotherapy can be traced largely or entirely to four non-specific factors/components.

Box 45.11 Frank's (1973) four non-specific factors/components involved in therapy

According to Frank, all psychotherapies:

- prescribe clearly delineated roles for therapist and client, with the former defined as an 'expert' possessing unique healing skills. This raises the client's hopes that help will be forthcoming;
- involve settings designed to be associated with the alleviation of psychological distress (a 'designated place of healing'), e.g. carpeted rooms with scholarly books and journals and prominently displayed diplomas;
- provide a convincing theoretical rationale for making sense of the client's problems. This instils a sense of confidence in clients and reassures them that their problems aren't incomprehensible or unique;
- include therapeutic rituals (prescribed tasks or procedures, such as SD and free association) that further enhance the client's faith in the therapist and the therapeutic rationale. These are akin to the ceremonial rituals of faith healers; they cultivate the impression that something deeply significant and mysterious is taking place.

Above all, these factors help to combat demoralisation, the universal malady that brings people to therapy. Most individuals who voluntarily seek treatment experience low self-esteem, despair, helplessness, alienation, and a profound sense of incompetence. All psychotherapies alleviate demoralisation by raising hopes and expectations of improvement, and by instilling feelings of confidence and self-worth (Mair, 1992).



Bandura (1977a) has integrated a number of findings into the proposal that the central element in psychological therapy is the cognitive change towards *self-efficacy*, the 'conviction that one can successfully execute a behaviour to produce a specified outcome' (see Chapter 35). This is brought about best through actual experience in facing previously feared or avoided situations.

The results of studies like those of Smith & Glass (1977) and Smith *et al.* (1980), which claimed that differences in the effectiveness of various therapies are negligible, support Frank's argument. But other outcome studies have shown that the more active, structured, directive therapies work best (at least for certain types of disorder): they're more heavily 'saturated' with Frank's non-specific factors than are other psychotherapies (Lilienfeld, 1995).

CONCLUSIONS

The whole concept of 'cure' is highly complex, and is itself defined differently from different theoretical and therapeutic perspectives (see Critical Discussion 45.2). The crux of Eysenck's (1952) review is how the effectiveness of psychotherapy should be assessed. He used Denker's (1946) criteria, namely:

- return to work and ability to carry on well in economic adjustments for at least five years
- complaint of no further or very slight difficulties, and
- making successful social adjustments.

During the Equinox ceremony in Ecuador, the indigenous shaman holds a golden pot, through which the Great Spirit is called, showing up like fire to purify the soul

These are all fairly tangible indicators of improvement. Even more so is the behaviour therapist's criterion that cure is achieved when patients no longer manifest the original maladaptive behaviour (e.g. the fear of spiders is eliminated). If these more stringent (or more easily measured) criteria of actual behaviour change are required before the therapist can be viewed as successful, then behaviour therapists do seem to be more effective than psychoanalysts or humanistic therapists (with cognitive approaches falling in between the two) (Rachman & Wilson, 1980; Shapiro & Shapiro, 1982).

But psychoanalytic therapists may answer the question 'Does therapy work?' by saying it's misleading, like asking whether friendship 'works'. It's an activity that people take part in, which is important to them, affects, moves, even transforms them (Oatley, 1984).

Because Eysenck is interested in comparing recovery rates (measured statistically), his assessment of the effects of therapy is purely *quantitative*. Psychoanalysts and those practising CCT are likely to be much more concerned with the *qualitative* aspects of therapy (such as the nature of the therapeutic process, and the role of the relationship between client and therapist). There are different kinds of questions one can ask when trying to assess the effects of psychotherapy. These approaches aren't mutually exclusive, however. The *interaction* between experimental research (where hypotheses can be tested scientifically) and therapy (where they can be tried out clinically) can influence theory development and therapeutic practices (Marzillier, 2004).

According to Lilienfeld (1995), the question 'Is psychotherapy effective?', although remarkably complex in some respects, may actually be too simple in others. As Paul (1966) observes, what we need to ask is 'What treatment, by whom, is most effective for this individual, with that specific problem, and under which set of circumstances?' This is to do with matching client, therapy and setting and, according to Wilson & Barkham (1994), is a question that still haunts psychotherapy research and disturbs therapists.

CHAPTER SUMMARY

- Both **clinical** and **counselling psychology** adopt the **scientist–practitioner model** of helping, but they've been more influenced by behavioural and humanistic approaches respectively.
- Treatments and therapies differ according to whether they're **somatic** or **psychological**, **directive** or **non-directive**, **individual** or **group**.
- The term '**psychotherapy**' is sometimes used to refer to all **non-somatic** treatments, and sometimes to **psychodynamic approaches/insight therapies**.
- Major groups of **antidepressant drugs** include **MAOIs**, **tricyclics** and **SSRIs**, including fluoxetine (Prozac).
- Chlordiazepoxide (Librium) and diazepam (Valium) are widely prescribed **anxiolytics**. They belong to the **benzodiazepines**.
- **Antipsychotic drugs** (**major tranquillisers/neuroleptics**) revolutionised the treatment of schizophrenia and other psychotic disorders. But they only treat the **positive symptoms** of schizophrenia, and cause serious side-effects.
- **Electroconvulsive therapy** (ECT) is now used mainly with depressive patients. While it's probably more effective than antidepressants, its benefits are only short-term, and it may cause long-term cognitive and emotional deficits.
- Although modern **stereotactic procedures** are much more precise than earlier **prefrontal lobotomies/leucotomies**, the use of **psychosurgery** remains extremely controversial. In the UK, it's used only as a last resort.
- According to Freud, **neuroses** involve the use of defences in an attempt to combat anxiety, but they're self-defeating, creating their own distress.
- The aims of **psychoanalysis** include providing insight. The analyst remains anonymous, which facilitates **transference**. **Interpreting** transference is a distinctive feature of psychoanalysis, as is the analyst's **counter-transference**.
- The client's **resistance** to interpretations of transference must itself be interpreted. **Free association** and **dream interpretation** are other major techniques.
- **Psychodynamic psychotherapy** represents a modified form of psychoanalysis. **Brief focal therapy** deals with a specific area of difficulty in a much shorter period of time than classical psychoanalysis.
- **Behaviour therapy** and **modification** refer to techniques based on **classical** and **operant conditioning** respectively. Both see adaptive and maladaptive behaviour as being acquired in the same way, and both reject the medical model.
- Eysenck and Rachman see the case of Little Albert as a model of how all **phobias** are acquired. But this can only account for the **initial learning** of phobias (through classical conditioning), not for their **persistence** (which occurs through negative reinforcement).
- According to Wolpe, the key principle in **systematic desensitisation** (SD) is **reciprocal inhibition**. It appears that neither relaxation nor the use of a hierarchy is necessary, and the 'active ingredient' seems to be **exposure** to the feared object/situation.
- **Implosion** (implosive therapy) is supplemented by the therapist's **stimulus augmentation**. Both implosion and **flooding** represent forms of '**forced reality testing**'. Flooding is thought to be the most effective of all treatments for phobias.
- **Aversion therapy** is particularly controversial when used with homosexuals. **Covert sensitisation** is aversion therapy that takes place in the patient's imagination, and is preferable on humanitarian grounds.
- Lovaas pioneered the use of **operant conditioning** with autistic children in an attempt to teach them to use speech. **Behaviour modification** has been used successfully with mentally retarded adults and children, both to reduce self-mutilation and to teach toilet training.
- Ayllon and Azrin pioneered the **token economy** (TE), based on the principle of **secondary reinforcement. Tokens** may be effective because of the way they change **staff** behaviour and attitudes, which is contrary to what learning theory principles would predict. TEs also raise some very important **ethical** issues.
- **Cognitive–behaviour therapy** (CBT) is based on the view that clinical disorders involve **faulty thoughts/cognitions**, which then produce maladaptive behaviour. **Cognitive restructuring** is a means to the end of changing emotions and behaviour.

- According to Ellis's **rational emotive therapy** (RET), **irrational thoughts** are the main cause of all types of emotional/behaviour disorders. Meichenbaum's **self-instructional training** (SIT) claims that neurotic behaviour is due to **faulty internal dialogues**.
- Beck's treatment of '**automatic thoughts**' aims to help clients understand the **cognitive triad** of depression. Therapy involves training in being more objective, separating fact from evaluation, and seeing things in less extreme ways.
- According to Rogers, threat, anxiety, and depression are responses to a **lack of congruence** between our experience and self-concept.
- The aim of **client-centred therapy** (CCT) is to allow the natural tendency towards **self-actualisation** to develop through the therapist's **genuineness/authenticity**, **unconditional positive regard** and **empathic understanding**.
- Evaluating the **effectiveness of therapy** involves both **outcome** and **process research**. Eysenck's landmark article claimed that recovery from neurosis following psychotherapy is no greater than the rate of **spontaneous remission**.
- Both the quantity and quality of subsequent outcome research have increased, showing psychodynamic therapies in a much more favourable light. One important improvement is the use of **meta-analysis**.
- Unlike drug trials, in psychotherapy it may be impossible to devise an **inactive placebo control**. If therapy effects don't exceed those of placebos, this is because the placebo itself raises hopes of improvement.
- Frank identifies four **non-specific factors** responsible for the success of psychotherapy. They help to combat demoralisation, the common factor shared by all those who seek therapeutic help. Related to this is Bandura's concept of **self-efficacy**.

Links with other topics/chapters

- Clinical psychologists are the largest single group of psychologists in the UK and the USA. The psychologist as *counsellor* and as *agent for change* are two of the seven major skills used by applied psychologists (Hartley & Branthwaite, 2000) (Chapter 1).
- The change toward family and marital/couple therapy seems to have been inspired by Laing's family interaction model of schizophrenia, which has been applied to less 'serious' problems that commonly occur in families and between partners (Chapter 44).
- *Alcoholics Anonymous* (AA), and other similar self-help organisations for drug abusers, victims of abuse, and so on, use group therapy (Chapter 8).
- One explanation of the placebo effect involves the release of brain *endorphins* (Chapter 4). It's also relevant to understanding *compliance with medication* among heart-attack patients (Chapter 12).
- Double-blind designs are used to prevent *experimenter effects/bias* (Chapter 3).
- The ego defence mechanisms form an important part of Freud's theory of 'normal' personality (Chapter 42), as well as his account of phobias and other neurotic disorders. This demonstrates the *dimensional* (as opposed to the *categorical*) *approach* to mental disorder (Chapter 43).
- Freud's concept of free association is relevant to the discussion about *free will and determinism* (Chapter 49).
- *Heterosexism,* along with *sexism* and *androcentrism* are forms of *bias* that permeate mainstream psychology (Chapter 47) and help to make it less than completely *objective* (Chapter 3).
- Criticisms of the use of therapy manuals in outcome research can be considered in terms of *internal vs external validity.* The better controlled the studies (thus increasing internal validity), the lower the external validity (relevance to actual therapy situations). This is a problem for psychological research in general (Chapter 3).

APPLICATION

CRIMINOLOGICAL PSYCHOLOGY

INTRODUCTION AND OVERVIEW

Not surprisingly, many of the questions we've discussed about the causes of behaviour have also been applied to crime and criminal behaviour. Psychology is just one of the several disciplines contributing to *criminology* (others being law, sociology, anthropology, economics, geography, politics, statistics, and psychiatry), and *criminological* (or *forensic*) *psychology* attempts to apply psychological principles to the criminal justice system (Harrower, 1998).

Defined in this way, the present chapter clearly overlaps with Chapter 21, which looked specifically at aspects of *cognitive psychology* (in particular memory and face recognition) in relation to the law. The two chapters are complementary. By discussing research into eyewitness testimony and face recognition, we were looking in Chapter 21 at one half of the 'crime–victim' equation. Here, the focus is on the person committing the crime, rather than on the witness (although witnesses aren't necessarily victims).

Because crime is a form of *social deviancy*, definitions and perceptions of crime overlap with the criteria discussed in Chapter 43 for defining psychological abnormality. Also, one theory of criminal behaviour holds that it reflects a particular type of personality disorder (see Chapter 44). Discussion of moral development (see Chapter 35), gender (Chapter 36), adolescence (Chapter 37), and personality (Chapter 42) are all highly relevant to any attempt to understand and explain criminal behaviour.

The Division of Forensic Psychology was recognised by the British Psychological Society in 1999.

WHO COMMITS CRIME?

ASK YOURSELF...

- Think of a criminal and what comes to mind (i.e. what's your *stereotype* of a criminal)?
- Are different types of crime likely to be committed by different kinds of criminal (in terms of age, gender, social-class background etc.)?

According to Hollin (1999), the strongest evidence relevant to predicting who'll commit crime comes from *longitudinal studies*. For example, Loeber *et al.* (1995) investigated predictive factors for the onset of conduct disorder, itself an established risk factor for later delinquency, in 177 males aged 8–17. They were followed up for 6 years, and data were collected on a range of psychological, psychiatric and social factors. Parental substance abuse, low socio-economic status (SES) and the child's resistance to discipline were important factors in eventual progression to diagnosed conduct disorder.

Longitudinal studies have helped illuminate our understanding of many criminological issues, including the relationship between age and crime, predictors of juvenile delinquency, and patterns of adult crime.

Age and offending

Delinquency rates for both males and females consistently increase from about age 8, peaking at 16–17, then rapidly declining into the late teens and early twenties. But is this due to increasing *prevalence* (more young people committing crimes) or a rise in *incidence* (young offenders committing more offences as they get older)? While these are difficult to separate, it's generally agreed that the rise in offending rates with age reflect increasing prevalence (Hollin, 1999).

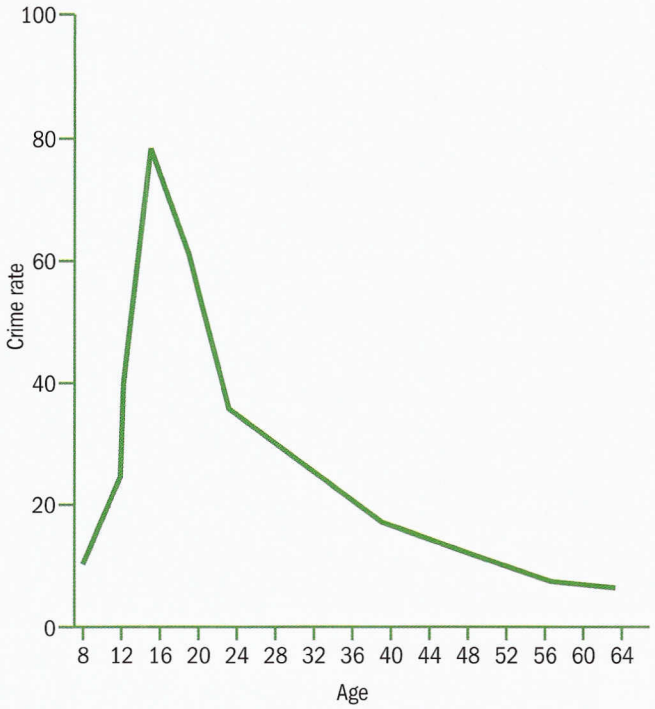

Figure 46.1 The relationship between age and crime (from Hollin, 1999)

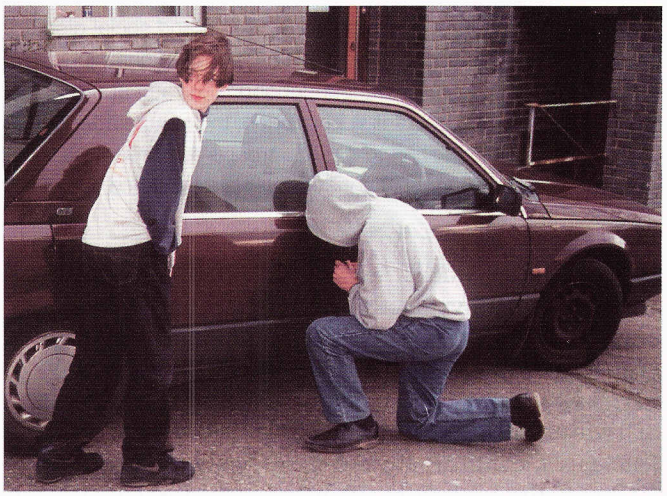
A defaced, grafittied statue of Winston Churchill



'Crime rate' refers to prevalence, in terms of the percentage of people of specific ages who commit offences. As Figure 46.1 shows, about 20 per cent of 12-year-olds, 80 per cent of 16-year-olds, 20 per cent of 36-year-olds, and 8 per cent of 52-year-olds commit crime.

Although juveniles commit a lot of crime, most is relatively trivial, including a large number of *status offences* (which apply only to young people, such as truancy, under-age drinking, driving a motor vehicle under age) as opposed to *index* (or *notifiable*) *offences* (serious offences, such as murder, rape and sexual assault, burglary, arson and robbery, which are criminal acts regardless of age). Young people commit both types, but status offences are much more common (Hollin, 1999).

The age–crime relationship also shows that most crime is 'adolescence-limited' (Moffitt, 1993); that is, most young people 'grow out' of delinquency by the time they're 18. So, what is it about being a teenager that makes criminal behaviour so much more likely than at any other age?

Box 46.1 Risk-taking and delinquency

- According to Hendry (1999), risk-taking has been one of the attributes of youth since adolescence became recognised as a distinct period of the lifespan. But it's an ill-defined concept. Is it part of the psychological make-up of youth, a necessary rite of passage en route to the acquisition of adult skills and self-esteem?
- Whatever the answer to these questions, risk-taking and delinquency can be seen as interrelated.
- The desire to identify with the peer group, especially in mid-adolescence (Coleman & Hendry, 1990) requires adherence to particular types of behaviour and roles, which imposes a group conformity even when antisocial activities are involved. Paradoxically, many juvenile crimes may reflect underlying values that are generally approved and encouraged by society (such as acquiring material possessions). 'Inappropriate' behaviours (such as drug and alcohol use, smoking, and sexual behaviour) may be 'used' to identify with adult patterns of behaviour (Hendry, 1999).
- Boys comprise the biggest proportion of juvenile offenders and enter the criminal justice system earlier than girls, and many juvenile crimes are *gendered* (such as joy-riding, a very 'male' crime). In the USA at least, young men are much more likely than young women to have several sexual partners, use alcohol and marijuana, drive recklessly, and engage in physically violent behaviour. They're consequently much more likely to die as a result of accidental injuries, homicides and suicides than young women. While black female teenagers are about four times more likely to be murdered than their white counterparts, black males are about eight times more likely to die this way than theirs (Sonenstein, 1999).

Car theft: a very male crime

Predictors of long-term offending

According to Hollin (1999), the most widely cited longitudinal study in the UK is the Cambridge Study in Delinquent Development. This began in 1961 with 411 males, aged eight to nine, and is still in progress, with over 90 per cent of the sample intact as they pass into their 40s. They've been repeatedly tested and interviewed throughout this period, and parents, peers, and teachers have also been interviewed. A vast amount and range of data have been gathered, dealing with parental child-rearing practices, economic factors, school behaviour and much more. Summary reports have been published by Farrington & West (1990) and Farrington (1995).

About 20 per cent were actually convicted as juveniles, 33 per cent were convicted up to the age of 25, and self-reported delinquency matched official records reasonably well.

KEY STUDY 46.1 The Cambridge Study in Delinquent Development (Farrington & West, 1990; Farrington, 1995)

The most important distinguishing characteristics, observed at age eight to ten, of later delinquents (measured by convictions and self-report) fell into six main categories:

- antisocial childhood behaviour, including troublesomeness in school, dishonesty and aggression
- hyperactivity/impulsivity/attention-deficit, including poor concentration, restlessness, daring and psychomotor impulsivity
- low intelligence and poor academic record
- family criminal record, including convicted parents, delinquent older siblings and siblings with behavioural problems
- family poverty, including low family income, large family size and poor housing
- poor parental child-rearing behaviour, including harsh and authoritarian discipline, poor supervision, parental conflict and separation from parents.

The intensity and severity of these personal and social disadvantages in childhood appear to be predictive of chronic offending in adolescence and adulthood. Over and above these factors, the age of first conviction, the school attended, employment, and moving to a more prosperous area were all related to patterns of criminal activity in adolescence.

In two independent studies, Elander *et al.* (2000a) confirmed that hyperactivity is a significant risk factor in boys, and Elander *et al.* (2000b) found that late-onset criminals (first conviction after age 22) were likely to have had a history of childhood and adolescent antisocial behaviour, major mental illness in adulthood, or both. Late-onset criminals are also more likely to be female.

By 18, the long-term offenders had adopted a lifestyle characterised by heavy drinking, sexual promiscuity, drug use, and minor crimes involving cars or group violence and vandalism. They were highly unlikely to have any formal qualifications, had unskilled manual jobs, and were often unemployed.

By 32, they were unlikely to be home-owners (and to be residentially mobile), had low-paid jobs, tended to have physically assaulted their partners and used a wide range of drugs. They had an extensive list of fines, probation and prison sentences. Overall, this was a socially dysfunctional existence. They committed more crimes while unemployed, and these were for financial gain – theft, burglary and fraud.

ASK YOURSELF...

- What bearing do you think close relationships have on offending?
- Might they be a *protective* factor? (See Chapter 32.)

The formation of close relationships in early adulthood was related to a *decrease* in offending: those who were married were less likely to offend than those who weren't, provided their partners weren't convicted offenders. But compared with non-offenders, they were more likely to have divorced or separated from their wives and children, and to have more conflict with their wives/partners (see Chapter 32).

However, there was still considerable overlap between offenders and non-offenders: not all the convicted men displayed these characteristics. Neither a disadvantaged background nor 'social failure' (Farrington, 1990) inevitably leads to crime, but it massively increases the risk of criminal behaviour (the 'good boys from bad backgrounds' phenomenon: Farrington & West, 1990).

Crime and gender

According to Heidensohn (1996):

Sex differences in criminality are so sustained and so marked as to be, perhaps, the most significant feature of recorded crime.

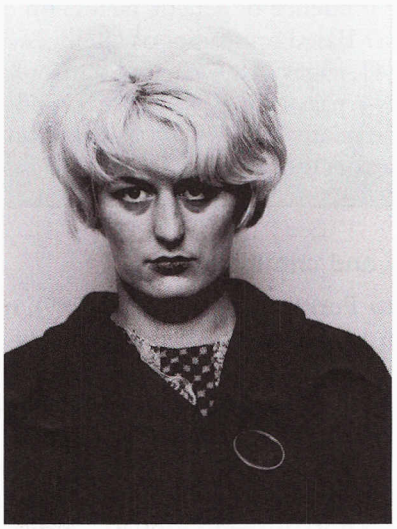
Lyon (1998) observes that 84 per cent of recorded crime is committed by men, who comprise 96 per cent of the prison population in England and Wales. One-third of men born in 1953 had been convicted of an offence by the age of 30. Similarly, Harrower (1998) maintains that:

Probably the most significant feature of both recorded and self-reported crime is that more males than females commit offences, particularly violent crimes, in spite of claims that women are becoming more violent in the 1990s ... or that, because of their inherent deviousness, they have always been more criminal but have simply been able to conceal it ...

Until recently, the 'maleness' of crime was taken as an accepted fact. In contrast to the 'ordinariness' of male crime, the few early studies of female offenders focused on their extraordinariness, as odd or ill creatures deviating from the norm (Lyon, 1998). In the 1970s, feminist perspectives began to develop in criminology, and the neglect of gender (especially women) was highlighted.

Women and crime

According to Lloyd (1995) in a book called *Doubly Deviant, Doubly Damned:*



... when women commit violent crimes they are seen to have breached two laws: the law of the land which forbids violence and natural law which says women are passive carers not active aggressors.

CRITICAL DISCUSSION 46.1 Women and violence

- Throughout the years of heated debate concerning Myra Hindley's release from prison, there seems to have been an implicit assumption that to have committed her crimes, she must be especially evil because *('ordinary') women don't commit (are incapable of) such crimes.*
- Pearson (1998, in *When She Was Bad: How Women Get Away With Murder)* tries to demolish the cherished myth that women aren't naturally aggressive. Pearson (a woman) blames feminists and society as a whole for refusing to see women as dangerous and destructive. We cannot bring ourselves to recognise the reality of female aggression and violence. So we find excuses for it, such as battered women syndrome, or premenstrual tension, or we see female killers (including Hindley and Rose West) as always junior accomplices of violent men.
- According to Smith (1998), the myth that Pearson tries to demolish tells only half the story. There's also a terror that women are innately *more cruel* than men, a sentiment summed up in Kipling's 'the female of the species is more deadly than the male'.
- It's been suggested that the criminal justice system is more 'chivalrous' (i.e. lenient) towards females, so that the gender difference in violent crime isn't in fact as large as official figures would make it seem (Harrower,

1998: see text below). But at the same time, there have been numerous cases in Britain of men killing their wives for trivial reasons, being found guilty of manslaughter and walking free after 5–6 years in prison, while women who kill their husbands tend to be convicted of murder and receive a life sentence (Smith, 1998).

- This injustice has led to the overturning of verdicts in celebrated cases like that of Sara Thornton, who was initially convicted of her husband's murder. She successfully argued that the court should have taken into account the cumulative effect of her husband's violence towards her, and she was released from jail.

Myra Hindley, who died in prison in 2002

Gender bias in the criminal justice system

According to Lyon (1998), there's considerable evidence that men and women are treated differently by the criminal justice system. Ideas and attitudes about what constitutes 'normal' male and female behaviour affect how female offenders are treated. Lyon gives three examples.

1. Hedderman & Gelsthorpe (1997) examined 13,000 cases of men and women convicted of shoplifting, violence and drug offences during 1991. For virtually every type of offence, women are treated more leniently than men. They also interviewed 200 magistrates about what they thought were the main influences on their decision-making. Women were considerably more likely than men to be discharged even when circumstances appeared to be entirely comparable. Magistrates were reluctant to fine women, especially those with dependent children, were more likely to define women offenders as troubled rather than troublesome, and to see their crimes as motivated by need rather than greed.
2. A high proportion of female offenders have themselves been the victims of crime (see Critical Discussion 46.1). Belknap (1996) found that prior victimisation, prostitution, running away and drug offences, and subsequent imprisonment were interrelated. Morris *et al.* (1994) surveyed large numbers of female prisoners in England and Wales, and almost half reported either being physically abused as children or the victims of domestic violence as adults. Another third reported sexual abuse. Similar findings were reported by HM Chief Inspector of Prisons (1997).

Some very young women become involved in prostitution through relationships with adults who offer accommodation and introduction to drug habits. The Children's Society (Lyon & Coleman, 1996) estimated that at least 5000 children under 16 are used for prostitution in Britain, and the number of girls of 16 or under who were convicted (1989–1994) rose by almost 80 per cent.

3. The most common female crimes are theft and property-related crimes, with a rising incidence of drug-related offences and crimes of violence against the person. Women are more likely to be in prison for the first time (about 70 per cent are 'first timers'), and are less likely to re-offend on release than males (under 50 per cent of female young offenders re-offend within two years, compared with 80 per cent of male young offenders).

Female prisoners are more likely to suffer from depression, to self-harm, abuse drugs or alcohol, seek medical help, and be prescribed (and often depend on) medication, compared with male prisoners. They're also more likely to be imprisoned far from home, and to be adversely affected by custody. Most have dependent children, for whom many retain considerable responsibility. Women in prison are also more likely to be charged with breaking prison rules and other discipline-related offences.

Women (especially black women) appear to face greater discrimination than men on release from prison in relation to finding housing and employment. Because they constitute a tiny minority of the prison population as a whole (4 per cent), women offenders may be regarded as unnatural or pathologically deviant (Lyon, 1998).

Men and crime

Feminist criminologists have helped to promote the view that 'masculinity' itself should be examined more closely in order to understand why so many young men commit offences – and are also the victims of crime (see Box 46.1). While at one time 'gender' was a 'code word' for women and femininity, it now refers to men and masculinity. Because of men's domination of all aspects of crime and the criminal justice system, it's only recently that their gender and the construction of their masculinity have been considered valid areas for study in their own right.

ASK YOURSELF...

- Why is it that males are much more likely to commit crimes than females? (See Chapters 2, 36 and 50.)

As Wilson & Herrnstein (1985) point out:

> Crime is an activity disproportionately carried out by young men living in large cities. There are old criminals, and female ones, and rural and small town ones, but to a much greater degree than would be expected by chance, criminals are young urban males.

According to Lyon (1998), two major explanations of the male domination of crime are *biological determinism* and *social constructionism*. Are men born to take risks, challenge authority, become violent and commit crimes? Or do they learn these behaviours, and is crime the context in which their masculine identity develops and is affirmed?

Over 80 per cent of all offenders are male, and this pattern is repeated internationally. So what is it about the cultural history and social construction of *masculinity* which ensures that so many young males become involved in crime (Harrower, 1998)? According to Lyon (1998), a new research focus on masculinity and crime seeks to challenge popular images of young men as yobs and thugs, and to question their 'natural 'involvement in offending. She also argues that:

> ... gender and crime can only be fully explored within the context of culture and society taking account of key variables such as race, class, family, economic circumstances and individual differences.

THEORIES OF CRIMINAL BEHAVIOUR

If, as we've seen, not all males commit crime and some females do, then there must be factors over and above gender that make people more likely engage in this sort of behaviour. Similarly, not all boys growing up in disadvantaged circumstances become adolescent or adult offenders. So, although being an urban male significantly increases your chances of committing crime, psychologists want to know what other influences are involved. In Hollin's (1997) terms:

> ... while the findings of the longitudinal surveys are important in describing the conditions associated with the onset of criminal behaviour, they also demand an explanation of how they cause delinquent behaviour. In other words, we still await a grand theory to explain the process by which the interaction between the young person and his or her environmental circumstances culminate in criminal behaviour.

In the meantime, we can draw on existing psychological theories, which may be applicable to criminal behaviour, without being theories of criminal behaviour as such.

ASK YOURSELF...

- How would Freud explain criminal behaviour? (See Chapter 35, pages 602–605.)
- How would Kohlberg explain criminal behaviour? (See Chapter 35, pages 609–613.)
- How would *social learning theorists* (such as Bandura) explain criminal behaviour? (See Chapter 29, pages 501–506, and Chapter 35, pages 615–618.)
- How could Bowlby's *maternal deprivation hypothesis* help to explain criminal behaviour? (See Chapter 32, page 551.)
- What methods would *behaviour geneticists* use to assess the influence of genetic factors on criminal behaviour? Based on studies of intelligence (see Chapter 41, pages 718–722) and schizophrenia (see Chapter 44, pages 796–798), what would you expect the relative influence of genetic and environmental factors to be?

Personality and criminality

According to Furnham & Heaven (1999), many studies have shown conclusively that personality factors are related to a wide range of antisocial, criminal, and delinquent behaviours. The vast majority of this research has been *cross-sectional* and has looked for links between criminal behaviour and the personality dimensions originally investigated by Eysenck, namely introversion–extroversion (E), neuroticism–emotional stability (N), and psychoticism (P).

Eysenck's personality theory

E, N and conditionability

ASK YOURSELF...

- How do you think Eysenck would explain criminal behaviour? (See Chapter 42, pages 736–738.)

For Eysenck, the criminal is a neurotic extrovert (someone who scores high on both N and E). N is linked to crime through *anxiety* (Eysenck & Eysenck 1970). High anxiety functions very much like a drive, which multiplies with habit, so someone who engages in delinquent behaviour is likely to persist in that behaviour if they're also high N scorers. The high E scorer is stimulus-hungry, engages in thrill-enhancing behaviours, and is more difficult to *condition*. Because 'conscience' is nothing more than a series of conditioned anxiety responses, the neurotic extrovert is *undersocialised* and has an underdeveloped conscience.

Cochrane (1974) reviewed a number of studies in which prisoners and control groups were given EPI questionnaires. Although prisoners are generally higher on N, they're *not* higher on E and, indeed, several studies have shown criminals to be *less* extroverted (and so more

introverted) than controls. However, Eysenck (1974) responded to these findings by claiming that the EPI largely measures the 'sociability' component of extroversion rather than the 'impulsivity' component, which is more relevant to conditionability. This represents a change to his earlier position, in which he equated 'sociability' (the capacity for socialisation) and 'conditionability'. Cochrane concludes that, at least in its original form, the theory has been discredited.

Even if prisoners were uniformly more extroverted and neurotic than non-prisoners, it could still be possible to explain these differences by reference to factors other than personality. For example, offenders who are caught (or found guilty) might differ in certain significant ways from those who aren't (or who aren't found guilty), such as the nature of the offence and the 'offender's' social status.

Farrington (1992) argues that the exact role of N depends on whether we're referring to 'official' or self-reported delinquency. 'Official' offenders are most often characterised by high N and low E scores (agreeing with Cochrane's findings), whereas self-reported offenders are the reverse: low N and high E. However, both forms of delinquency are related to high P (see below).

Heather (1976) argues that:

> The notion that such a complex and meaningful social phenomenon as crime can ever be explained by appealing to the activity of individual nervous systems would be laughable were it not so insidious.

What makes the theory insidious, he says, is that it 'places the fault inside individuals rather than in the social system where it almost always belongs'.

Psychoticism and crime

P is more strongly correlated with crime than either N or E (Eysenck & Eysenck, 1970, 1985; Eysenck & Gudjonsson, 1989). According to Furnham & Heaven (1999), it's well established that high P scorers are also aggressive, uncaring, troublesome, inhumane, insensitive to others' needs and feelings, tend to not experience guilt, prefer strange and unusual things, and appear foolhardy (Eysenck & Eysenck, 1970). Howarth (1986) found that high P scorers are impulsive, tend to be un-cooperative, rigid, and lacking sensitivity, and Claridge (1981) found a close association between P and overt aggressiveness and impulsivity.

Not surprisingly, in view of all these findings, P scores are well able to discriminate between criminals and non-criminals (Eysenck & Gudjonsson, 1989).

KEY STUDY 46.2 A longitudinal study of delinquency and personality (Heaven, 1996b)

- Heaven studied 282 14-year-olds over a two-year period, measuring delinquency, E, P and self-esteem.
- The best longitudinal predictor of later delinquency was P, with E and low self-esteem both having little impact.
- Although the importance of P supports previous findings, the overall effect was quite small: the three factors accounted for just over 16 per cent of the variance in delinquency scores when first measured, and only 6 per cent two years later. So, over time, the impact of personality on the maintenance of delinquency scores seems to have been rather limited (Furnham & Heaven, 1999).
- Heaven suggests that factors (dimensions or *domains*) such as E are too broad and insensitive to capture the full subtlety of developmental change. Lower-order factors (or *facets*), such as excitement-seeking, trust, impulsiveness, and venturesomeness might capture these subtleties better. This conclusion was supported by a separate study involving delinquency and the 'big five' personality factors (Heaven, 1996a: see Chapter 42, page 742).

According to Furnham & Heaven (1999):

> Clearly much more work needs to be done on assessing the interaction between personality and external factors such as family life, peer pressure, group norms and so on. Indeed, evidence also suggests that physiological factors (e.g. heart rate) may be implicated in the personality–behaviour link ... This kind of research needs to be undertaken increasingly if we are to achieve a much more comprehensive understanding of the psychology of criminality.

Antisocial personality disorder (psychopathy)

Definitions and classification

'Psychopathy' was first included in the 1959 Mental Health Act, which defined it as:

> ... a persistent disorder or disability of mind (whether or not including subnormality of intelligence) which results in abnormally aggressive or seriously irresponsible conduct on the part of the patient and requires or is susceptible to medical treatment.

According to the Mental Health Act 1983:

> Psychopathy means a persistent disorder or disability of mind (whether or not including significant impairment of intelligence) which results in abnormally aggressive or seriously irresponsible conduct on the part of the person concerned.

Because it was felt strongly that those with psychopathic disorder should only be compulsorily detained if there was a reasonable prospect of response to treatment, the diagnostic criteria in the definition were separated (in the 1983 Act) from the susceptibility to treatment clause (Prins, 1995). These are contained in other sections of the Act, which made compulsory admission for treatment available only if it can be stated that medical treatment is likely to alleviate or prevent a deterioration in the individual's condition. According to Prins:

> This was an important proviso because it recognised the difficulties involved in treating psychopaths, but kept the door open

> for therapeutic optimism ... It also serves to emphasise the fact that the term psychopathic disorder should be used sparingly and not as a 'dustbin' label for those clients or patients who are merely difficult, un-cooperative or unlikeable ...

A working group was set up by the Department of Health and the Home Office (1992) to review the treatment options for individuals with psychopathic disorder, their appropriate location, and arrangements for treatment. The 1994 report called for considerably more research into the nature of the disorder, its classification and management.

The report also recommended replacing the term 'psychopathic disorder' with 'personality disorder'. In fact, DSM–IV-TR uses the term '*antisocial personality disorder*' (APD), and ICD–10 refers to '*dissocial personality disorder*' (DPD).

Box 46.2 The major characteristics of antisocial personality disorder (APD)

Individuals diagnosed with APD:

- lack tender feelings and concern for others' feelings, so that relationships are shallow and unstable; sex is purely 'functional' (if male) and they're highly promiscuous
- appear to have no family loyalty and commit their crimes alone; they're basically loners
- have superficial charm and are often socially skilled; their charm can be very disarming and enables them to manipulate and exploit others for their own gain
- behave callously, as in inflicting pain or degradation or acting cruelly towards others
- act violently towards their marriage partners, and their children, whom they may also neglect, resulting in separation and divorce
- are impulsive and fail to strive consistently towards a goal, lacking a purpose in life; this may be reflected in an unstable employment record
- have low tolerance of frustration and a tendency towards violence, which often causes repeated criminal offences; this may begin with petty acts of delinquency, but progresses to callous, violent crimes; their lack of guilt and failure to learn from experience result in behaviour that persists despite serious consequences and legal penalties
- they commit a disproportionate number of violent crimes.

(Based on Gelder *et al.*, 1999; Prins, 1995)

According to Hart & Hare (1996), 50–80 per cent of adult male prison inmates meet the DSM criteria for APD. But Mitchell & Blair (2000) argue that:

> Unless we desire to label almost all individuals who engage in antisocial behaviour as presenting with a psychiatric disorder, we must consider these diagnoses to be unsatisfactory.

Fred and Rosemary West, husband and wife serial killers

Hare has developed an alternative, arguably more successful, method for identifying individuals whose antisocial behaviour may reflect an actual disorder. This is the *Revised Psychopathy Checklist* (PCL-R: Hare, 1991), which measures two distinct but correlated factors:

- *factor 1* – affective and interpersonal characteristics, including superficial charm, pathological lying, manipulation, lack of empathy, shallow affect and lack of guilt
- *factor 2* – chronic and versatile antisocial lifestyle, including proneness to boredom, parasitic lifestyle, impulsivity, juvenile delinquency and violation of release conditions.

Essentially, the psychopathic individual is someone with an emotional disorder who also has a high risk of antisocial behaviour.

PCL–R has proved very reliable and is very useful in risk assessment. For example, within 3 years of release, 80 per cent of those judged to be psychopathic (based on PCL–R) had violated the conditions of their release, compared with just 25 per cent of the non-psychopaths. A meta-analytic study by Hemphill *et al.* (1998) found that psychopathic offenders were three times more likely to re-offend and four times more likely to re-offend violently within a year of release, compared with non-psychopathic offenders.

What causes APD?

Display of the full disorder seems to involve a complex interaction between social environment and biological predispositions. In particular, social environment (such as SES) influences factor 2, while factor 1 is unrelated to SES. This suggests that biological make-up determines whether individuals show emotional difficulties. But these emotional factors are only *risk factors:* an adverse social environment provides the conditions needed for the disorder to develop (Mitchell & Blair, 2000).

ASK YOURSELF...

- Which explanation of *schizophrenia* mirrors this account of APD? (See Chapter 44, page 798.)

Like other forms of criminality (see Key Study 46.1), parental antisocial attitudes, inconsistent discipline, physical punishment, broken homes and childhood separations all predict high APD scores in adolescence (Forth, 1995). However, the quality of parenting doesn't influence the probability of conduct disorders in children who display the emotional difficulties associated with APD – but they do in most children (Wootton *et al.*, 1997).

Box 46.3 Emotional processing in APD individuals

The two main explanations of how emotional processing differs in APD individuals and 'normals' are (a) abnormalities in the experience of fear, and (b) a fundamental inability to empathise.

- As proposed by Eysenck (see text above), socialisation is achieved through *fear conditioning*. Normally, individuals learn to avoid antisocial behaviour because they're 'frightened' of the consequences. Those with impaired fear cannot be socialised in this way, so they don't learn the usual avoidance responses. However, much of the literature fails to support punishment as an effective means of socialisation, stressing instead the importance of *empathy induction*.
- Sad, and possibly fearful, expressions may serve a similar function in humans to submissive postures (*appeasement gestures*) in non-humans (Blair, 1995). APD individuals are less sensitive, specifically, to others' sadness and fear (as opposed to expressions of anger, for example), and so are more difficult to socialise. They don't seem to feel the same aversion to the thought of other people's pain as do 'normal' individuals.

The brain and APD

It appears that the *amygdala* functions atypically from an early age in people with APD. It's long been known that the amygdala plays a crucial role in the processing of emotion, especially fear. Just like people with APD, normal humans and non-humans suffering damage to this area don't show normal *fear conditioning* (Spence, 2004: see Box 46.3) or *startle reflex potentiation/priming* (LeDoux, 1998). The amygdala has also been shown to be involved in human emotional response to sad facial expressions (Blair *et al.*, 1999). But this response is absent in individuals with APD.

KEY STUDY 46.3 Brain abnormalities in murderers (Raine *et al.*, 1997)

- Raine *et al.* wanted to provide direct evidence for the claim that murderers pleading not guilty by reason of insanity (NGRI) have brain dysfunction.
- Using PET scans, glucose metabolism (GM) was measured in a variety of brain regions and structures while participants engaged in a continuous performance challenge task. (The significance of GM is that glucose is the principal type of fuel used by neurons when transmitting information. So, the *lower* the GM, the *less* the activity in any particular part of the brain).
- The participants were 41 murderers pleading NGRI and controls matched for age and sex. Based on previous research (with both violent offenders and non-violent controls), Raine *et al.* expected to find differences between the two groups only in specific brain areas.
- As far as *cortical* areas are concerned, the murderers were expected to show *lower* GM in the *prefrontal cortex* (PFC), the *superior parietal gyrus* and the *left angular gyrus* (also an area within the parietal lobe). This prediction was supported. Also as expected, *no* differences were found in the *temporal lobe* or the *cingulate*.
- As far as *subcortical areas* are concerned, the murderers compared with the controls showed reduced GM in the *corpus callosum* and they also showed *abnormal asymmetries* in the *amygdala, thalamus* and the *medial temporal lobe* (including the *hippocampus*). This means that the murderers showed a bias towards increased *right-hemisphere* activity. Also as expected, there were *no* differences found in the *basal ganglia, midbrain* or *cerebellum*.

Raine *et al.* suggest that a bias towards activity in the right hemisphere might mean that processing of negative emotion (such as anger and aggression) might be subject to less inhibition from the left hemisphere. In other words, those emotions would be less controlled. Lower than normal activity in the PFC, parietal cortex and corpus callosum suggests a deficit in the integration of information needed to modify and inhibit behaviour. For example, increased blood flow to the PFC usually occurs when people are engaged in planning some future behaviour. People with PFC damage are often unable to plan ahead, and live in the 'here and now', controlled by currently physically present stimuli and situations (Luria, 1973). Abnormalities in the hippocampus and amygdala suggest deficiency in forming and utilising emotionally coloured perceptions and memories (Toates, 2001).

It's likely that at least some of the murderers in the Raine *et al.* study would be diagnosed as having APD. In a later study, Raine *et al.* (2000) used MRI to study the brains of 21 volunteers with APD. They were found to have 11 per cent less prefrontal grey matter than those without APD, the first evidence of a structural brain deficit in APD.

CRITICAL DISCUSSION 46.2 What should be done with potential criminals?

ASK YOURSELF...

- What conclusions can we draw from Raine *et al.*'s findings?

- If it can be demonstrated that people with APD have a brain disorder, then isn't it reasonable to blame their violent behaviour on the brain deficit, absolving the offender of blame and responsibility ('He couldn't help himself – his relative lack of grey matter in his PFC prevented him from controlling his behaviour as normal people can')? This is obviously relevant to the NGRI plea made by the 41 murderers.
- But all we can safely conclude from Raine *et al.*'s study is that certain brain abnormalities are *correlated* with certain types of violent behaviour – *not* that any differences in brain activity actually *cause* the violent behaviour. It's possible that developing violent tendencies actually changes the function of certain brain areas, rather than vice-versa. Indeed, Raine *et al.* themselves suggest that both the brain abnormalities and the violent behaviour could be the result of one or more social, psychological, cultural or situational factors.
- Advances in neuroscience make it increasingly possible to identify people with the same neurological abnormalities as the violent criminal but *who haven't yet offended.* Should such people be removed from society and put in psychiatric 'quarantine' to protect themselves and potential victims (Spence, 2004)? Many in the USA are calling for the screening of potential violent criminals (Gibbs, 1995), and the idea has already been mooted by the UK government in proposals for a new Mental Health Act. If passed, psychiatrists may be called upon to detain people judged to be at risk of committing violent crimes.

ASK YOURSELF...

- What do you think about this proposal?
- Even if the science is reliable, is it ethically acceptable?

- Spence (2004) regards this as a disturbing prospect, not least because of the difficulty in predicting how much threat any particular individual poses.
- Spence cites a study claiming that to prevent *one* violent act over the course of a year, *six* potential offenders would have to be detained for the rest of their lives:

... As well as infringing the liberty of innocent people, this would clearly be a waste of public resources. Far from keeping potential killers off the street, the introduction of psychiatric quarantine would demonise the innocent and probably deter those with neurological abnormalities from seeking medical help ... (Spence, 2004).

Can APD be treated?

Controversy surrounding APD rivals that which has always surrounded schizophrenia, and raises some of the same fundamental issues, such as reliability and validity (see Chapter 44). According to Smith (2000), 'Personality disorder is surely the greyest of grey areas', and the diagnosis, far from showing the way to treatment, is in fact extremely unhelpful for nurses and patients alike. Believing that patients have a personality disorder can excuse us from trying to establish meaningful and helpful interactions with them.

While the general consensus is that APD – and personality disorder in general – is notoriously resistant to treatment, schizophrenia, for example, was also once thought to be untreatable. Mitchell & Blair (2000) are confident that research in the near future may allow us to treat APD too.

CRITICAL DISCUSSION 46.3 Do suicide bombers have APD?

- According to Silke (2002), there are many myths surrounding terrorists and terrorism. Surely one of the most common, though, is that terrorists in general, and perhaps suicide-bombers in particular, are crazed fanatics, psychopaths (i.e. they have APD), who are completely immune to the suffering of their victims (making the terrorists homicidal or suicidal maniacs).
- It's comforting to think that suicide terrorists are different from the rest of us, either by virtue of a personality (and related brain) disorder, or because they are poor and ignorant, with little prospect of a decent future and are driven to act by unbearable political oppression and religious fanaticism (usually Islamic) (Bond, 2004). Although there are many cases which suggest that terrorists *do* possess a degree of callousness and fanaticism not usually found in 'normal' populations, these assumptions are wrong on almost every count.

Reem Raiyshi, the first 'Martyr Mother' – a Palestinian suicide bomber who killed four Israelis in Gaza in 2004, leaving behind two young sons

- Recent research by psychologists and anthropologists suggests that suicide bombers are no less rational, no less sane, no worse educated, no poorer and no more religious than anyone else, and have none of the risk factors normally associated with suicide, such as depression and history of attempted suicides, schizophrenia or substance abuse (Bond, 2004).
- The link with religion is complicated, because most Islamic terrorist groups use religious propaganda (largely the promise of paradise) to prepare recruits for suicide missions. But suicide terrorism isn't exclusive either to religious groups or Islamic culture. For example, leading perpetrators are the Tamil Tigers, a Marxist-Leninist group who come from Hindu families but are themselves hostile to religion. There were also the Japanese kamikaze pilots who flew their planes into enemy ships during the Second World War.
- Suicide terrorism is an *organisational* phenomenon (not the act of a crazed individual). The decision to engage in it is political and strategic, and the aim is always to coerce a government into withdrawing from territory the group considers its homeland, sometimes by attacking fellow countrymen seen to be supporting them (as in ongoing attacks against police stations in Iraq).
- Against this background of a sense of injustice and persecution, the move from being a 'disaffected individual' to a 'violent extremist' is usually facilitated by a catalyst (trigger) event. For example, the shooting (captured on television) by Israeli soldiers of a father and his 12-year-old son as they cowered behind a water barrel in September 2000 at Netzarim, triggered a dramatic resurgence in Palestinian–Israeli conflict.
- Most suicide bombers have had at least one relative or close friend killed, maimed or abused at the hands of enemies. They join terrorist groups in an angry and vengeful frame of mind, already intent on taking part in suicide attacks (Silke, 2002).
- Although there's some evidence that suicide bombers are more 'marginal' people, more influenced by the group, more vulnerable, fragile, and narrow-minded:

> *... researchers believe that in the vast majority of cases, individual psychology is not the determining factor ... All you need, it seems, is a peculiar mix of social, cultural and political conditions for a group to make the decision. After that, it could be anyone, school boys and mothers included ... (Bond, 2004)*

OFFENDER PROFILING

ASK YOURSELF...

- What does offender profiling mean?
- Can you give any examples – fictional or real?

CASE STUDY 46.1: Adrian Babb, serial rapist

- One Sunday afternoon in June 1987, a 75-year-old woman was returning to her flat in a tower block. As she entered the lift, a young man stepped in with her. Once the lift door had closed, he pinned her to the wall and forced her to the rooftop. There he raped her.
- A few months later, Canter, a criminological psychologist, was given details of this and a number of related assaults, all against elderly and often frail victims in tower blocks in the same area of Birmingham. The information indicated a small area of the city in which the offender was likely to be living, his domestic circumstances and likely criminal record. It also pointed out his lack of experience in committing crimes, and the consequent likelihood that he'd have left forensic evidence at one or more of the crime scenes.
- One of the principles on which *offender profiling* is based is that the details of exactly how the crime was committed (the stock-in-trade of detectives) is fundamental – there are many ways of raping and killing. The common themes of aggressive control and violent assault can be played out with many variations. For example, this serial rapist responded to aspects of his victims' discomfort. When one victim complained of the cold concrete on her bare flesh, he put some of the clothing he'd removed from her on the floor beneath her. This was typical of his style of assault. By contrast, other rapists delight in demeaning and degrading their victims.
- These details suggested that he'd be known as helpful and considerate by those who didn't know of his violent assaults. He turned out to be Adrian Babb, a well-regarded, 20-year-old swimming pool attendant. His fingerprint was found at the scene of one of his crimes, he pleaded guilty to seven rapes, and was sentenced to 16 years in prison.

(Based on Canter, 1994a)

According to Harrower (2000), *offender profiling* (or *criminal personality, psychological,* or *behaviour profiling*) is seen as the sexy speciality of forensic psychology largely as a result of Fitz (Robbie Coltrane) in *Cracker.* But the poetic licence allowed in that TV series hasn't been particularly helpful to psychology as a discipline.

A brief history

Harrower (1998) traces what's now called offender profiling (OP) to 1888, when a police surgeon (Thomas Bond) compiled a detailed description of Jack the Ripper. During World War II, Walter Langer, a psychiatrist, was asked to compile a profile of Hitler by the Office of Strategic Studies. He constructed a psychodynamic personality profile, which took considerable account of Hitler's parents' influence on him, especially his mother. The aim was to provide sufficient insight into

his personality to allow an interrogation strategy to be developed should he be captured. He accurately predicted that Hitler would commit suicide if he faced defeat.

According to Brown (2000), OP began when the police and a psychologist, James Brussel, collaborated in apprehending a serial bomber in New York during the 1950s.

CASE STUDY 46.2 The 'mad bomber' (Brussel, 1968)

- Brussel was asked to profile the kind of person who could be capable of carrying out the bombings. He produced a remarkably accurate profile, deriving his characteristics from deductions based on crime scene data and the psychodynamic interpretation of letters written by the bomber and slashes left on the underside of theatre seats (where the bombs were secreted).
- For example, the letters were written in a stilted English, suggesting a grammatical style reminiscent of Eastern European immigrants. These groups had settled mainly in Connecticut. The duration and single-mindedness of the attacks suggested an obsessive and conformist personality.
- George Metesky, Slavic by birth, was eventually arrested and charged, following investigative leads suggested by the profile. He was in his early fifties, living in Connecticut with two unmarried sisters. At the time of his arrest, he was wearing a conventional double-breasted suit, obsessively buttoned up.

(Based on Brown, 2000)

Further development of OP was undertaken by the FBI Behavioural Science Unit during the 1980s. In the UK, interest in OP developed sharply following the Peter Sutcliffe ('Yorkshire Ripper') case. This involved the setting up of sophisticated computer-based retrieval systems. Now, all good detectives operate through their own 'computer bases' (their brains), enabling them to form pictures based on stored experience (Prins, 1995: see below).

Robbie Coltrane in *Cracker*. But forensic psychology isn't all it's cracked up to be

What exactly is OP?

According to Copson (1996), there's no universally accepted definition of OP. It's really a 'term of convenience' covering techniques in which the behaviour shown in a crime is used to draw inferences about the likely offender. For Turco (1993), OP involves:

> ... the preparation of a biographical 'sketch' gathered from information taken at a crime scene, from the personal history and habits of a victim, and integrating this with known psychological theory.

The resulting sketch can be used by police officers to reduce their list of suspects, or to offer a new line of enquiry. Traditionally, the only clues noted at crime scenes tended to be 'hard' evidence (such as blood stains). But OP also allows recognition of other, less visible clues, such as choice of victim, location, nature of the assault, what's said or not said to the victim, and so on (Harrower, 1998: see Case Studies 46.1 and 46.2). According to Harrower:

> The overall aim of profiling is to narrow the field of investigation, drawing inferences about the offender's motivation and personality from evidence left at the crime scene ...

OP is most useful when the scene reflects psychopathology, such as sadistic assaults. 90 per cent of profiling involves murder and rape, although it's also used in arson, burglary, robbery, obscene phone calls and the new crime of stalking (see Box 46.5, page 848).

Current approaches

A distinction is commonly made between the American and British approaches (Brown, 2000; Harrower, 1998).

The American approach

In 1979, FBI investigators began interviewing a growing number of imprisoned serial killers and sex murderers (including Charles Manson and Ted Bundy). The 36 who were interviewed were classified as *organised* (24) or *disorganised* (12). The former planned their crimes, the victims were targeted, and the element of control was important. They were of average intelligence, socially and sexually competent, and had intimate partners. By contrast, the disorganised were impulsive, carried out unplanned attacks, made no attempt to conceal the bodies, may have known the crime scenes beforehand and/or the victims, were socially inadequate, and were loners. These descriptions provided theoretical models which would allow accurate profiles to be compiled based on examination of the crime scene (Harrower, 1998).

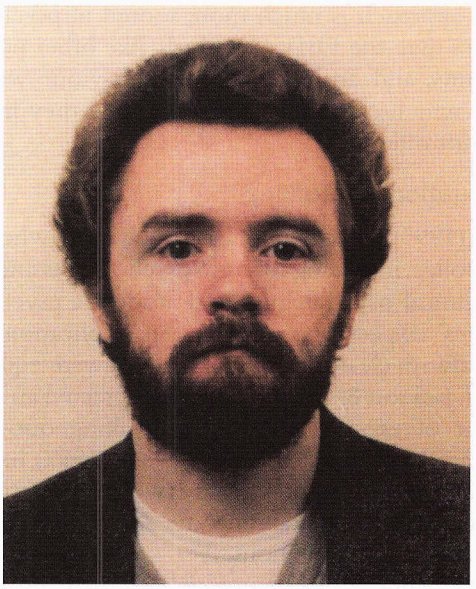
According to Ressler (one of the interviewers) *et al.* (1988), sex killers tend to be white, unmarried males, either unemployed or unskilled workers, with previous

histories of psychiatric illness or alcoholism, dysfunctional family backgrounds, and a sexual interest in voyeurism, fetishism, and pornography. Their crime scenes provided information which could then be used to identify them as organised or disorganised.

The FBI now trains profilers worldwide, but it doesn't consider profiles to be suitable in all investigations: they're most useful where there's some indication of psychopathology. According to Harrower (1998):

> The basis of the FBI's approach is that the crime scene and the offender's *modus operandi* will reveal indicators of individual pathology, which may fit into a pattern already observed from case studies of incarcerated offenders.

Douglas *et al.* (1986) describe the FBI four-stages approach as:



- *data assimilating,* in which as much information as possible is collected
- *crime classification,* when the type of crime is identified
- *crime reconstruction,* during which hypotheses about the behaviour of victims are generated
- *profile generation,* describing demographic and physical characteristics of the likely perpetrator.

According to Holmes (1989), the aims of profiling within this approach are to:

- reduce the scope of an investigation by providing basic information regarding the core social and psychological variables of the offender's personality (e.g. race, age range, employment status and type, educational background and marital status)
- allow some prediction of future offences and their location
- provide a psychological evaluation of belongings found in the offender's possession (e.g. souvenirs, trophies from previous offences)
- provide strategies for interviewing offenders which can take account of individual differences, but profit from experience with offenders who've displayed a common pattern of offending.

The British approach

This is associated with Britton (1997) and Canter (1994a, 1994b: see Case Study 46.1). Canter was originally approached by the Metropolitan Police in 1985 to advise whether psychology could contribute to criminal investigations. In 1986 he became involved in what was initially a serial rape investigation, but later developed into a notorious serial murder case. He helped secure the arrest of John Duffy, convicted in 1988 of two murders and five rapes, for which he was given seven life sentences. The accuracy of his description of Duffy astonished both the police and the media.

John Duffy, serial rapist-killer

Box 46.4 Canter's approach to profiling

- As indicated in Case Study 46.1, the criminal leaves 'psychological traces' or 'shadows' in committing a crime:

  ... tell-tale patterns of behaviour that indicate the sort of person he is. Gleaned from the crime scene and reports from witnesses, these traces are more ambiguous and subtle than those examined by the biologist or physicist ... They are more like shadows [which] ... can indicate where investigators should look and what sort of person they should be looking for ... (Canter, 1994b)

- In addition, we all operate within a social context, so there's an implicit *social* relationship between the offender and victim. This again will offer major clues to the pattern of the offender's life. Sensitive and detailed examination of victims' testimony can reveal speech patterns, interests, obsessions, and ways of behaving which will also have occurred in the offender's daily life. For example, rapists may treat their victims as they treat most of the women in their lives – in the case of Adrian Babb, he actually showed consideration for their feelings, which reflected a generally considerate attitude to other people: see Case Study 46.1.
- According to Boon & Davies (1992), Canter and his colleagues have found five aspects of the criminal and his behaviour to be particularly revealing: residential location, criminal biography, personal characteristics, domestic and social characteristics, and occupational and educational history. Geography is especially important: offenders will operate in areas they know and feel comfortable in (a relatively short distance from their homes).

Canter's approach is much more rooted in psychological principles than the FBI's. Criminals, like other people, act consistently, and analysis of their behaviour will reveal patterns which can offer clues as to how they live when they're not offending.

An evaluation of profiling

Copson (1995) described 30 British profilers who worked for the police, including forensic psychologists and psychiatrists, clinical psychologists, and academic psychologists. Detectives' expectations about the application of OP weren't always clear, and not all profiles were equally well regarded. Jackson & Bekerian (1997) detected an unfortunate 'war of experts' potentially breaking out between various academic profilers, and Stevens (1997) has argued for continued cooperation between detectives and academics, so that OP can become a systematised tool for use in criminal investigations.

OP has undoubted potential if used properly by trained professionals (Harrower, 1998). But how successful is it? Holmes (1989) cites FBI data claiming that 192 cases of profile construction (1981) resulted in 88 arrests, but OP was believed to have contributed to an arrest in just 17 per cent of the arrests. Others (e.g. Oleson, 1996) point out that the FBI's methodology may be fundamentally flawed: there's no control group against which to compare the evidence obtained from offenders, no mention of the statistical techniques used to analyse the data, and much of the interview data is accepted at face value.

In the UK, Copson & Holloway (1997) surveyed detectives who'd worked on 184 cases in which OP had been used. They believed it had produced identification of offenders in less than 3 per cent of cases, and 'helped to solve' the crime in 16 per cent. They conclude that:

> Profiling can work very well, but certainly not in the way some practitioners, let alone dramatists, would have you believe. There is nothing in our findings to support the notion that complex offender characteristics can be predicted with any great accuracy. In fact, with some people you would be better off tossing a coin.

According to Harrower (2000):

> ... both training and practical experience are vital in developing profiling expertise, and productive liaison between the police and psychologists is the way forward in order to achieve both investigative and clinical objectives.

As she points out, the phenomenon of serial murder and the development of OP have clearly captured the public imagination – and a growing number of psychology students want to become forensic psychologists.

Box 46.5 Stalking and its management

- Stalking has come to describe persistent attempts to impose on another person unwanted communications (by phone, e-mail, letters, or graffiti) or contact (via approaches, following or maintaining surveillance). Associated behaviours include sending unsolicited gifts, ordering or cancelling services on the victim's behalf (e.g. pizzas and electricity supply), and stalking can also involve threats, escalating to both physical and sexual violence (Mullen *et al.*, 2000).
- The term was first used in the American media in the late 1980s to describe repeated intrusions upon the famous, usually by disordered fans. It then generalised, first to include harassment of women by ex-partners, and later to all forms of ongoing harassment that induces fear in the victim, regardless of the relationship.
- Mullen *et al.* (1999) have proposed a typology of stalking with five categories. These aren't mutually exclusive, but the typology provides a clinically useful guide when assessing or considering future management, and it predicts the likely duration of the stalking.

Jodie Foster, famous stalkee

Intimacy seekers invariably have serious psychopathology, and are sometimes psychotic. The initial aim of management is to bring their disorders under reasonable control through a combination of drugs and structured psychotherapy. Long-term cessation of stalking is improved if their social isolation can be decreased and their capacity for social interaction improved. They're indifferent to threats or the reality of fines or imprisonment.

Rejected stalkers are rarely mentally ill, but are often inadequate, dependent, angry men with marked social and interpersonal problems. They're quite often substance abusers. They'll often desist when threatened with imprisonment, but may also benefit from therapy.

Incompetent stalkers are the easiest to manage. Telling them to stop is usually sufficient. Most have stopped before receiving psychiatric help, but there's a very high rate of recidivism. The only long-term solution is to improve their social skills and social networks.

Resentful stalkers are difficult to engage in therapy, and are often substance abusers. Their basic personality is

often suspicious and sensitive, and they become resentful of therapists just as they have of others who've crossed their path in the past. But once engaged, they do respond.

Predatory stalkers are best seen as sex offenders. The right mix of legal punishment and therapeutic intervention will relieve both the victim and the stalker of the burden of this destructive behaviour.

THE TREATMENT OF OFFENDERS

According to Honderich (1993), there are two distinct views (both implicit and explicit) as to why people commit crime:

- the individual is a rational agent with free will – an individual's circumstances reflect his/her choices (see Chapter 49)
- we're all, to a greater or lesser degree, products of our environments.

Related to the 'free will' viewpoint are two policies:

- provide as few opportunities as possible for choosing a criminal act
- when people are caught, make the consequences as painful as possible to deter them from future offending.

Based on the second view:

- if environmental conditions are implicated in the cause of the crime, then change is needed in the environment (primarily, the social structure)
- the adverse effects on individuals resulting from the environment need to be addressed.

According to Hollin (1999), in practice these viewpoints and policies crystallise into the debate about the relative effectiveness of punishment and treatment in crime prevention (see Box 46.5).

Situational crime prevention

If crimes are the end result of criminals seizing the opportunity to make a personal, usually financial, gain, then why not look at the opportunity as well as the criminal (Hollin, 1999)? This is exactly the approach of *situational crime prevention:* analysing and changing the environment in an effort to prevent crime.

ASK YOURSELF...

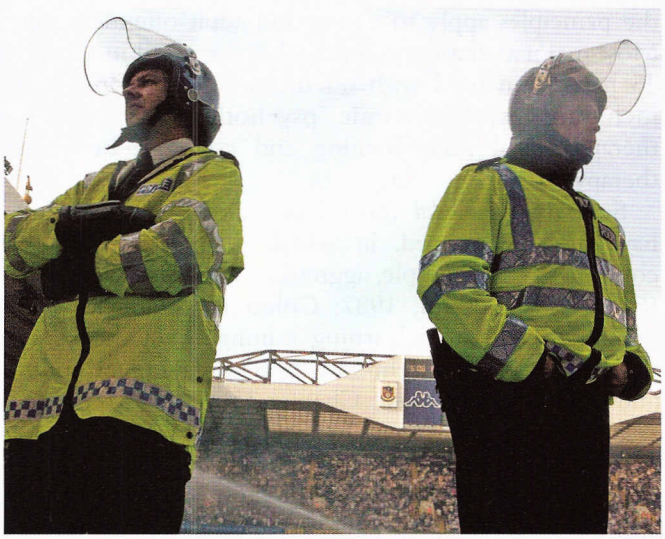
- Try to think of some practical ways in which situational crime prevention could be achieved (see Chapter 21).

The most straightforward way is to *reduce the opportunity for successful crime,* by removing and protecting the target. For example, replacing phone coin boxes with cards, introducing night transport systems to ensure safety of late-night workers, and installing more car alarms, immobilisers and home security systems.

In addition, *increasing the risk of detection* can be achieved through formal surveillance in places where there's opportunity for crime. For example, increased police presence at football matches and city centres at pub-emptying times, CCTV, electronic 'tagging' of offenders, and neighbourhood watch schemes.

ASK YOURSELF...

- Can you see any potential problems with situational crime prevention – both practical and ethical?



When offenders are deterred from committing a criminal act, is crime actually being reduced or merely displaced onto other victims, times and situations? There are also civil liberties issues relating to tagging, CCTV and other forms of surveillance.

Deterrence is also found in the harsh punishment approach (from fines to 'life sentences').

Punitive prison regimes

ASK YOURSELF...

- Do you believe that offenders should be punished rather than rehabilitated?
- Are your reasons moral, as opposed to pragmatic (such as what is most likely to prevent re-offending)?
- Are punishment and rehabilitation necessarily mutually exclusive?

Increased police presence at football matches is a form of situational crime prevention, increasing the risk of detection

Reconviction rates (*recidivism*) of people discharged from prisons in England and Wales are 54–70 per cent (Lloyd *et al.*, 1994), depending on the type of offender, length of follow-up, and so on. *Punishment-oriented regimes* seek to reduce these figures by making the experience of prison so aversive as to deter ex-prisoners from re-offending. These include the 'short, sharp shock' (introduced in the UK in the 1980s) and 'boot camps', an American concept involving a short period of incarceration in a strict military environment, with a rigid daily schedule of hard labour, drill and ceremony, and physical training (Mackenzie & Souryal, 1995).

Mackenzie & Shaw (1990) found that compared with offenders sentenced to traditional prisons, those who went to boot camp were more positive about their prison experiences and their futures, and held more prosocial attitudes. Mackenzie & Souryal (1995) also reported a range of positive outcomes for the boot-camp group, such as being drug-free, physically healthy, believing that the regime had helped them, and an overall positive effect on their families. However, those sent to boot camp had been convicted of non-violent crimes, and had less serious criminal histories (Hollin, 1999).

Evidence regarding recidivism is very mixed. But there's little evidence that the military regime would successfully change future behaviour if the 'criminogenic needs of the offenders are not being addressed' (Mackenzie *et al.*, 1995).

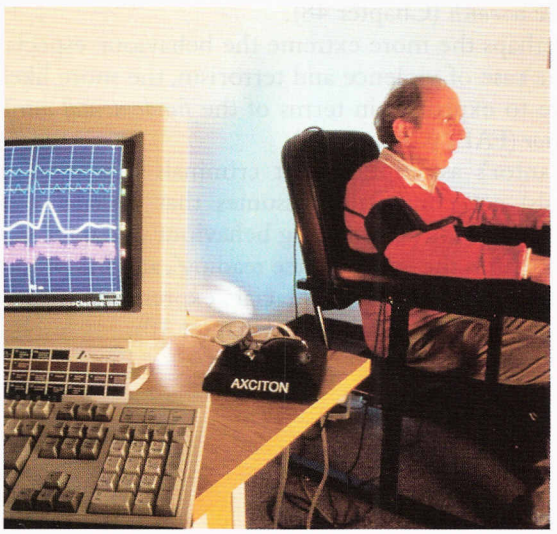
According to Farrington (1995), findings from longitudinal studies point to the need for strategies to improve young people's academic achievement, interpersonal skills, parental child-rearing practices, and to reduce poverty (see Key Study 46.1).

Treatment programmes

There's a vast literature on *therapeutic approaches,* especially with young offenders (e.g. Hollin & Howells, 1996), but the principles apply to young and adult offenders alike. Most major therapeutic approaches discussed in Chapter 45 have been used with offenders (and see Box 46.5), including psychodynamic psychotherapy, behaviour therapy, social skills training and cognitive–behaviour therapy (CBT).

Several *multimodal* (mixed or 'eclectic') programmes have also been used, in which several methods are combined. For example, aggression replacement training (Glick & Goldstein, 1987; Goldstein & Glick, 1996) combines structured learning training (including social skills and social problem-solving training), anger control and moral education (see Chapter 35).

Does treatment work?



There are hundreds of outcome studies, using different types of intervention, conducted in different settings, and using different measures of 'success'. As with outcome studies in the treatment of mental disorder, *meta-analytic studies* allow general conclusions to be drawn (see Chapter 45). According to Hollin (1999):

- overall, there's a 10 per cent reduction in recidivism when treated offenders are compared with no-treatment controls; but this figure conceals tremendous variability between different programmes
- the best results will be obtained with medium- to high-risk offenders, using structured/focused/directive approaches (in practice, this usually means behavioural methods that incorporate a cognitive component)
- treatment in the community has a stronger effect on delinquency than residential programmes.

Research update 46.1 Lie detection: old and new

- In 2001, Terry Harrington's brainwaves were presented as evidence in a court in Iowa, USA. He'd been sentenced 23 years earlier to life imprisonment for a murder he claims he didn't commit. The brainwave evidence was an attempt to win the right to appeal by proving that Harrington's brain showed no glimmer of recognition for the crime scene (Phillips, 2004a). The initial attempt failed, but the brainwave method was deemed admissible, and Harrington was finally freed in 2003 (McKie, 2004).
- The method, called *brain fingerprinting* (BF), was developed by Lawrence Farwell. It uses a network of scalp electrodes to pick up brainwave signals (P300) that have long been known to be associated with novelty: the signal is emitted exactly 300 milliseconds after the brain is confronted with a stimulus that has special significance to that individual (such as a victim's face or the gun used to rob him).
- In 2004, Farwell used BF to show that (the unfortunately named) Jimmy Ray Slaughter – convicted and sentenced in Oklahoma, USA, to death for the murder of his daughter and partner – lacked any knowledge of key details of the crime scene, including the positions of the victims' bodies. BF is now expected to play a key role in attempts to block Slaughter's execution (McKie, 2004).
- BF is just the kind of technique that could be used to detect *potential* offenders (see Critical Discussion 46.2).
- The UK Home Secretary announced in May 2004 that paedophiles and other sex attackers face compulsory American-style lie-detector tests (*polygraphs*) before and after being freed from prison. Police and probation officers could block early release or order offenders back to jail if they're liable to reoffend. Although polygraphs are routinely used in the USA, they're regarded as too unreliable to be admissible by British courts (Morris, 2004).
- Changes in heart rate, respiration and sweating on the palms and fingers are recorded when the participant responds with a 'yes' or 'no' answer to a series of

questions that have previously been explained so that there'll be no surprises. The hope is that the guilty suspect will show an increase in these measures of autonomic nervous system activity when asked a question relevant to the crime. Generally, accuracy is better than chance, but there can be sizeable *false positives* (innocents judged guilty) and *false negatives* (guilty people judged innocent). A report by the US National Academy of Sciences (2002) concluded that there was no scientific evidence that the polygraph is valid for purposes of national security screening (Ekman, 2003).

Computerised polygraph test in progress

- Ekman (2003), who has advised judges, the FBI and the CIA, has developed a 'face-reading' technique, which he calls the Facial Acting Coding System (FACS). It doesn't measure emotion directly, but 'objectively scores all facial muscular movement', which helps to identify the signs that betray a lie. These might come in very fast facial movements, revealing an emotion that someone is trying to conceal.

CHAPTER SUMMARY

- **Longitudinal studies** help us understand the relationship between **age and crime**, with delinquency peaking at 16–17 years. This reflects increasing **prevalence** and a very high **crime rate** at this age.
- Most juvenile crimes are **status offences** (as opposed to **index/notifiable offences**). Also, most crime is 'adolescence-limited', which can be explained partly in terms of the greater **risk-taking** of adolescents, and partly in terms of **peer group pressure**.
- Several childhood factors have been shown to predict later offending, including **low intelligence/poor school record**, a **family criminal record**, **family poverty**, and **poor parental child-rearing practices**.
- Although neither a disadvantaged background nor 'social failure' inevitably lead to crime, they massively increase the risks of criminal behaviour.
- Most crimes, especially violent crimes, are committed by males. This has led to a view of **women** who commit murder as **doubly deviant**, breaking both the law of the land and the 'natural law' relating to women's 'nature'.
- There's considerable evidence of **gender bias** and **gender differences** in the **criminal justice system**. These are apparent in sentencing, the link between committing crime and being the victim of crime, the kind of crimes committed, and behaviour inside prison and following release.
- Two extreme explanations of **male domination** of crime are **biological determinism** and **social constructionism**. All the major theoretical perspectives within psychology as a whole have been/can be applied to criminal behaviour.
- **Personality factors** (or **domains**), such as **N**, **E**, and especially **P** are related to a wide range of antisocial, criminal and delinquent behaviours. However, more specific **facets** may be more valid predictors of developmental change.
- **Antisocial personality disorder** (APD) or **psychopathy** has long been implicated in criminal behaviour, especially violent crimes. One very controversial aspect of APD is its **treatability**.
- At the heart of APD seems to lie an **emotional disorder**, which represents a **risk factor** for the development of the full disorder. For antisocial behaviour to occur, there needs to be an adverse social environment.
- There's growing evidence of **brain abnormalities** that are **correlated** with APD and murder, but this doesn't allow us to infer that the brain abnormalities actually *cause* the violent behaviour. The possibility of detecting **potential** violent criminals raises fundamental legal and ethical issues.
- A common perception of **terrorists** in general and **suicide bombers** in particular is that they're insane fanatics. But the evidence suggests that they're mainly quite ordinary individuals caught up in violent situations involving the occupation of their homeland by an invading enemy.
- **Offender profiling** (OP) has been used to investigate a variety of crimes. But it's most useful when the crime scene reflects **psychopathology**, as in (serial) murder and rape.
- There are differences in the approaches used by the FBI and British forensic psychologists, who place more emphasis on **psychological principles**. An important example is that offenders will tend to operate close to where they live.
- The use of **polygraphs** is to be used with paedophiles and other sex offenders in the UK, and in the USA **brain fingerprinting** (BF) is admissible evidence in court cases.

- **Situational crime prevention** involves both reducing the opportunity for successful crime and increasing the risk of detection. But criminals may simply **displace** their offences onto other victims, places and times.
- **Punitive prison regimes** may help to reduce **recidivism rates** among less serious criminals, while **treatment programmes** are most successful with medium- to high-risk offenders.
- A wide variety of treatments and therapies has been used, including **multimodal** approaches. **Structured** methods used in **non-residential settings** seem to be the most effective.

Links with other topics/chapters

- If risk-taking is a rite of passage into adulthood, it is so only for *adolescents* in western culture, where initiation ceremonies are lacking, and where young people face contradictory definitions of their social status (Chapter 37).
- Criminology has notoriously ignored the fact of gender, preferring to offer universal theories of crime based on research with males (Harrower, 1998). This is an example of the *androcentric bias* (Chapter 47).
- Eysenck's attempt to explain crime in terms of high E and N scores on the EPI is an example of a *reductionist* explanation (Chapter 49).
- According to Lorenz's *ethological theory of aggression,* inborn sensitivity to appeasement gestures has evolved in order to reduce violence between members of the same species (Chapter 29).
- APD individuals seem to lack this inborn sensitivity, as well as the normal *empathic responses* to others' distress (Chapter 30).
- The study of potential violent offenders, together with its practical implications, is an example of *socially sensitive research* (Chapter 48).
- Perhaps the more extreme the behaviour, especially in the case of violence and terrorism, the more likely we are to explain it in terms of the *fundamental attribution error* (FAE) (Chapter 23).
- Cantor's assumption that criminals (like non-criminals) act consistently assumes that *personality* is the major factor determining behaviour (Chapter 42).
- Ekman is the 'guru of face reading', and has proposed a number of universal facial expressions related to particular *emotional states* (Chapter 10).

BIAS IN PSYCHOLOGICAL THEORY AND RESEARCH

INTRODUCTION AND OVERVIEW

Mainstream academic psychology, modelling itself on classical, orthodox, natural science (such as physics and chemistry), claims to be *objective, unbiased,* and *value-free.* Collectively, these aims form the *positivist* view of science, or *positivism* (see Chapter 3). As applied to the study of humans, this implies that it's possible to study people as they 'really are', without the psychologist's characteristics influencing the outcome of the investigation in any way.

This chapter shows that a view of psychology as unbiased and value-free is mistaken. Two major forms of bias, *sexism* and *ethnocentrism* (which relate to gender and culture respectively) permeate much psychological theory and research.

Much of the chapter's content is relevant to the topic of prejudice and discrimination. As we saw in Chapter 25, prejudice and discrimination can be understood as characteristics of individuals or of social groups, institutions, and even whole societies. With bias in psychological theory and research, it's sometimes individual psychologists, and sometimes 'psychology as a whole', that are guilty.

GENDER BIAS: FEMINIST PSYCHOLOGY, SEXISM AND ANDROCENTRISM

Not surprisingly, most of the criticism of mainstream psychology regarding its gender bias has come from *feminist psychology,* which Wilkinson (1997) defines as:

> ... psychological theory and practice which is explicitly informed by the political goals of the feminist movement.

While feminism and feminist psychology can take a variety of forms, two common themes are the valuation of women as worthy of study in their own right (not just in comparison with men), and recognition of the need for social change on behalf of women (Unger & Crawford, 1996).

Feminist psychology is openly political and sets out to challenge the discipline of psychology for its inadequate and damaging theories about women, and for its failure to see power relations as central to social life (Unger & Crawford, 1992). More specifically, it insists on exposing and challenging the operation of male power in psychology:

> Psychology's theories often exclude women, or distort our experience by assimilating it to male norms or man-made stereotypes, or by regarding 'women' as a unitary category, to be understood only in comparison with the unitary category 'men' ... Similarly, psychology [screens out] ... the existence and operation of social and structural inequalities between and within social groups ... (Wilkinson, 1991)

Psychology obscures the social and structural operation of male power by concentrating its analysis on people as individuals (*individualism*). Responsibility (and pathology) are located within the individual, to the total neglect of social and political oppression. By ignoring or minimising the social context, psychology obscures the mechanisms of oppression. For example, the unhappiness of some women after childbirth is treated as a problem in individual functioning (with possible hormonal causes), thus distracting attention away from the difficult practical situation in which many new mothers find themselves (Wilkinson, 1997: see Critical Discussion 44.3, page 787).

Box 47.1 Some major feminist criticisms of psychology

- Much psychological research is conducted on all-male samples, but then either fails to make this clear or reports the findings as if they applied equally to women and men.
- Some of the most influential theories within psychology as a whole are based on studies of males only, but are meant to apply equally to women and men.
- If women's behaviour differs from men's, the former is often judged to be pathological, abnormal, or deficient in some way (*sexism*). This is because the behaviour of men is, implicitly or explicitly, taken as the 'standard' or norm against which women's behaviour is compared (*androcentrism* – male-centredness, or the *masculinist bias*).
- Psychological explanations of behaviour tend to emphasise biological (and other internal) causes, as opposed to social (and other external) causes (*individualism*). This gives (and reinforces) the impression that *psychological sex differences* are inevitable and unchangeable. This reinforces widely held *stereotypes* about men and women, contributing to the oppression of women (another form of sexism).
- Heterosexuality (both male and female) is taken, implicitly or explicitly, as the norm, so that homosexuality is seen as abnormal (*heterosexism*).

ASK YOURSELF...

- Try to think of (at least) one example for each of the five major criticisms of psychological theory and research made in Box 47.1.
- Regarding the fourth point, how does this relate to attribution theory as discussed in Chapter 23?

The feminist critique of science

In many ways, a more fundamental criticism of psychology than those listed in Box 47.1 is feminists' belief that scientific enquiry itself (whether this be within psychology or not) is biased.

Psychology's claims to be a science are based on its methods (especially the experiment), and the belief that it's a value-free discipline. But can scientific enquiry be neutral, wholly independent of the value system of the human scientists involved? According to Prince & Hartnett (1993):

> Decisions about what is, and what is not, to be measured, how this is done, and most importantly, what constitutes legitimate research are made by individual scientists within a sociopolitical context, and thus science is ideological.

Many feminist psychologists argue that scientific method is gender-biased. For example, Nicolson (1995) identifies two major problems associated with adherence to the 'objective' investigation of behaviour for the way claims are made about women and gender differences.

- The experimental environment takes the individual 'subject's *behaviour*', as distinct from the 'subject' herself, as the unit of study. Therefore, it becomes deliberately blind to the behaviour's *meaning,* including its social, personal, and cultural contexts. As a result, claims about gender differences in competence and behaviour are attributed to *intrinsic* qualities (either the product of 'gender role socialisation' or biology) as opposed to contextual qualities. This is another reference to *individualism* (see Box 47.1).
- Experimental psychology, far from being context-free, takes place in a very specific context which typically disadvantages women (Eagly, 1987). In an experiment, a woman becomes anonymous, stripped of her social roles and the accompanying power and knowledge she might have achieved in the outside world. She's placed in this 'strange' environment, and expected to respond to the needs of (almost inevitably) a male experimenter who's in charge of the situation, with all the social meaning ascribed to gender power relations.

The belief that it's possible to study people 'as they really are', removed from their usual sociocultural contexts (in a '*de-contextualised*' way), is completely invalid:

> Psychology relies for its data on the practices of socialised and culture-bound individuals, so that to explore 'natural' or 'culture-free' behaviour (namely that behaviour unfettered by cultural, social structures and power relations) is by definition impossible ... (Nicolson, 1995)

Feminist psychologists offer a critical challenge to psychological knowledge on gender issues by drawing on other disciplines, such as sociology. According to Giddens (1979), for example:

> There is no static knowledge about people to be 'discovered' or 'proved' through reductionist experimentation, and thus the researcher takes account of context, meaning and change over time.

ASK YOURSELF...

- Do you agree with Nicolson's claim that all human behaviour is 'culture-bound'?
- What about 'instinctive' behaviours, such as eating, drinking and sex: does culture play a part here too? If so, in what ways?

(These questions are equally relevant to the section on culture bias.)

Some practical consequences of gender bias

According to Kitzinger (1998), questions about sex differences (and similarities) aren't just scientific questions, they're also highly political. Some answers to these questions have been used to keep women out of universities, or to put them in mental hospitals. Other answers have been used to encourage women to go on assertiveness training courses, or to argue that women should have all the same rights and opportunities as men. In other words, the science of sex differences research is always used for political reasons:

> However much psychologists may think or hope or believe that they are doing objective research and discovering truths about the world they are always influenced ... by the social and political context in which they are doing their research ... (Kitzinger, 1998)

Celia Kitzinger, lesbian feminist psychologist

For Prince & Hartnett (1993), scientific psychology has *reified* concepts such as personality and intelligence (treating abstract or metaphorical terms as if they were 'things' or entities):

> ... and the scientific psychology which 'objectively' and 'rationally' produced means of measuring these reifications has been responsible for physical assaults on women such as forced abortions and sterilisations.

Between 1924 and 1972, more than 7500 women in the state of Virginia alone were forcibly sterilised, in particular, 'unwed mothers, prisoners, the feeble-minded, children with discipline problems'. The criterion used in all cases was mental age as measured by the Stanford–Binet intelligence test (Gould, 1981).

Having convinced society that intelligence 'exists' in some objective way, and having produced a means of measuring it, psychologists could then promote and justify discrimination against particular social groups. Another example of the use of intelligence tests to justify blatant discrimination (although not specifically against women) involved the army alpha and beta tests, which

influenced the passing of the 1924 Immigration Restriction Act in the USA.

CRITICAL DISCUSSION 47.1 Psychology's influence on immigration policy in the USA

- Debates in Congress leading to passage of the Immigration Restriction Act (1924) continually made reference to data from the army alpha and beta tests.
- *Eugenicists* (who advocate 'selective breeding' in humans in order to 'improve' genetic stock) lobbied for immigration limits and for imposing harsh quotas against nations of inferior stock. In short, southern and eastern Europeans, who scored lowest on the army tests, should be kept out. The eugenicists battled and won one of the greatest victories of scientific racism in American history. 'America must be kept American', proclaimed President Coolidge as he signed the bill.
- Throughout the 1930s, Jewish refugees, anticipating the Holocaust, sought to emigrate, but were refused admission. Estimates suggest that the quotas barred up to six million southern, central and eastern Europeans between 1924 and 1939:

We know what happened to many who wished to leave, but had nowhere to go. The paths to destruction are often indirect, but ideas can be agents as sure as guns and bombs ... (Gould, 1981)

The results of Army intelligence tests influenced immigration policy in the USA in the 1920s. The quotas were based on the arrivals before 1890. Immigrants up to that year were mainly Nordic, and supposedly more intelligent than the Southern and Eastern Europeans who arrived later

In the 1993 preface to *In a Different Voice* (1982), Gilligan says that at the core of her work on moral development in women and girls was the realisation that within psychology, and in society at large, 'values were taken as facts'. She continues:

> In the aftermath of the Holocaust ... it is not tenable for psychologists or social scientists to adopt a position of ethical neutrality or cultural relativism ... Such a hands-off stance in the face of atrocity amounts to a kind of complicity.

While the example she gives is clearly extreme, it helps to illustrate the argument that not only do psychologists (and other scientists) have a responsibility to make their values about important social and political issues explicit, but failure to do so may (unwittingly) contribute to prejudice, discrimination, and oppression. These considerations are as relevant to a discussion of the *ethics* of psychological research as they are to gender (and culture) bias, and are discussed in more detail in Chapter 48.

The masculinist bias and sexism: A closer look

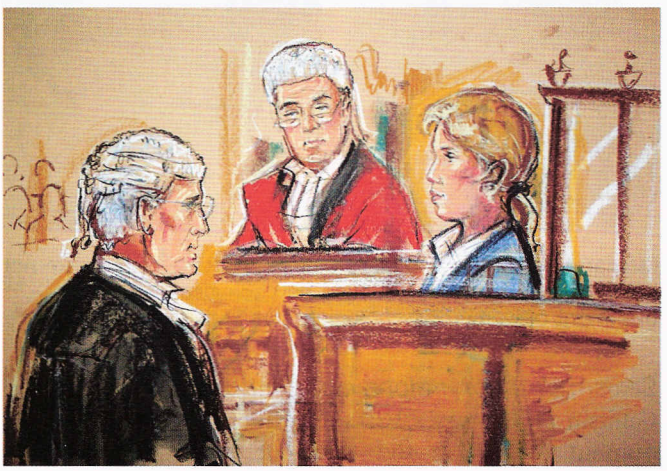
Box 47.1 (page 856) identified the masculinist bias (*androcentrism*) and sexism as two major criticisms of mainstream psychology made by feminist psychologists. While each of these can take different forms, emphasis here will be given to (a) the argument that men are taken as some sort of standard or norm, against which women are compared and judged, and (b) gender bias in psychological research.

The male norm as the standard

According to Tavris (1993):

> In any domain of life in which men set the standard of normalcy, women will be considered abnormal, and society will debate woman's 'place' and her 'nature'. Many women experience tremendous conflict in trying to decide whether to be 'like' men or 'opposite' from them, and this conflict is itself evidence of the implicit male standard against which they are measuring themselves. This is why it is normal for women to feel abnormal.

Tavris gives two examples of why it's normal for women to feel abnormal. First, in 1985, the American Psychiatric Association proposed two new categories of mental disorder for inclusion in the revised (third) edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-III-R: see Chapter 43). One was *masochistic personality*. In DSM-II, this was described as one of the psychosexual disorders, in which sexual gratification requires being hurt or humiliated. The proposal was to extend the term so that it became a more pervasive personality disorder, in which one seeks failure at work, at home, and in relationships, rejects opportunities for pleasure, puts others first (thereby sacrificing one's own needs), plays the martyr, and so on.



While not intended to apply to women exclusively, these characteristics are associated predominantly with the female role. Indeed, according to Caplan (1991), it represented a way of calling psychopathological the behaviour of women who conform to social norms for a 'feminine woman' (the 'good wife syndrome').

In short, such a diagnostic label was biased against women, and perpetuated the myth of women's masochism. The label was eventually changed to 'self-defeating personality disorder', and was put in the appendix of DSM-III-R.

ASK YOURSELF...

- If you were proposing a parallel diagnosis for men who conform to social norms for a 'masculine man', what characteristics would this have to include, and what would you call it?
- Could you justify including sadism in the diagnostic criteria for conformist men?

Tavris's second example of why it's normal for women to feel abnormal concerns *causal attributions* made about men's and women's behaviours. When men have problems, such as drug abuse, and behave in socially unacceptable ways, as in rape and other forms of violence, the causes are looked for in their upbringing. Women's problems, however, are seen as the result of their psyches or hormones. Explaining women's problems in this way is another form of individualism, with the further implication that it could have been different for men (they are the victims of their childhood, for example), but not for women ('that's what women are like'). (But see Chapter 46.)

Do women get into trouble with the law only for 'internal' reasons?

The 'mismeasure of woman' and alpha bias

According to Tavris, the view that man is the norm and woman is the opposite, lesser or deficient (the problem) constitutes one of three currently competing views regarding the 'mismeasure of woman' (meant to parallel Gould's, 1981, *The Mismeasure of Man,* a renowned critique of intelligence testing: see Critical Discussion 47.1 and Chapter 41). It's the view that underpins so much psychological research designed to discover why women aren't 'as something' (moral, intelligent, rational) as men (what Hare-Mustin & Maracek, 1988 call *alpha-bias:* see below). Alpha bias also underlies the enormous self-help industry: women consume millions of books and magazines advising them how to become more beautiful, independent, and so on. Men, being 'normal', feel no need to 'fix' themselves in corresponding ways (Tavris, 1993).

Women are consumers of vast amounts of alpha bias

Box 47.2 A demonstration of alpha bias

- Wilson (1994) maintains that the reason 95 per cent of bank managers, company directors, judges, and university professors in Britain are men is that men are 'more competitive', and because 'dominance is a personality characteristic determined by male hormones'.
- Wilson also argues that women in academic jobs are less productive than men: 'objectively speaking, women may already be over-promoted'. Women who do achieve promotion to top management positions 'may have brains that are masculinised'.
- The research cited by Wilson to support these claims comes partly from the psychometric testing industries which provide 'scientific' evidence of women's inadequacies, such as (compared with men) their 'lack' of mathematical and spatial abilities. Even if women are considered to have the abilities to perform well in professional jobs, says Wilson, they have personality defects (in particular, low self-esteem and lack of assertiveness) which impede performance:

  These differences [in mental abilities, motivation, personality and values] are deep-rooted, based in biology, and not easily dismantled by social engineering. Because of them we are unlikely to see the day when the occupational profiles of men and women are the same.

(From Wilson, 1994; Wilkinson, 1997)

ASK YOURSELF...

- Try to identify examples of individualism in Box 47.2.
- Can you formulate some arguments against Wilson's claims?

Wilson is combining alpha bias with individualism in order to argue that women are 'naturally' deficient in the 'male' qualities needed to achieve in certain occupations. He's also assuming that the research he draws on to make his claims isn't itself gender-biased.

Sexism in research

The American Psychological Association's Board of Social and Ethical Responsibility set up a Committee on Nonsexist Research, which reported its findings as *Guidelines for Avoiding Sexism in Psychological Research* (Denmark *et al.*, 1988). This maintains that gender bias is found at all stages of the research process:

- question formulation
- research methods and design
- data analysis and interpretation, and
- conclusion formulation.

The principles set out in the *Guidelines* are meant to apply to other forms of bias too: those concerned with race, ethnicity, disability, sexual orientation and socio-economic status.

Box 47.3 Examples of gender bias at each stage of the research process

- **Question formulation:** It's assumed that topics relevant to white males are more important and 'basic' (e.g. the effects of TV violence on aggression in boys: see Chapter 29), while those relevant to white females, or ethnic minority females or males, are more marginal, specialised, or applied (e.g. the psychological correlates of pregnancy or the menopause).
- **Research methods and design:** Surprisingly often, the sex and race of the participants, researchers, and any stooges/confederates who may be involved, aren't specified. Consequently, potential interactions between these variables aren't accounted for. For example, men tend to display more helping behaviour than women in studies involving a young, female confederate 'victim' (see Chapter 30). This could be a function of either the sex of the confederate or an interaction between the confederate and the participant, rather than sex differences between the participants (which is the conclusion usually drawn).
- **Data analysis and interpretation:** Significant sex differences may be reported in very misleading ways, because the wrong sorts of comparisons are made. For example:

  'The spatial ability scores of women in our sample is significantly lower than those of men, at the 0.01 level'. You might conclude from this that women cannot or should not become architects or engineers. However, 'Successful architects score above 32 on our spatial ability test ... engineers score above 31 ... twelve per cent of women and 16 per cent of men in our sample score above 31; eleven per cent of women and 15 per cent of men score above 32'. What conclusions would you draw now? (Denmark et al.*, 1988)*

- **Conclusion formulation:** Results based on one sex only are then applied to both. This can be seen in some of the major theories within developmental psychology, notably Erikson's *psychosocial theory* of development (1950: see Chapters 37 and 38), Levinson *et al.*'s (1978) *Seasons of a Man's Life* (see Chapter 38), and Kohlberg's theory of moral development (1969: see Chapter 35). These all demonstrate *beta-bias* (Hare-Mustin & Maracek, 1988), and are discussed further below.

(Based on Denmark *et al.*, 1988)

Margaret Washburn and Mary Calkins; if these women are not household names, it is because psychological literature's treatment of women psychologists has kept them invisible

Sexism in theory: alpha and beta bias

Gilligan (1982) gives Erikson's theory of lifespan development (based on the study of males only) as one example of a sexist theory, which portrays women as 'deviants' (*alpha bias*). In one version of his theory, Erikson (1950) describes a series of eight *universal* stages, so that, for both sexes, in all cultures, the conflict between identity and role confusion (adolescence) precedes that between intimacy and isolation (young adulthood). In another version, he acknowledges that the sequence is *different* for a female, who postpones her identity as she prepares to attract the man whose name she'll adopt, and by whose status she'll be defined (Erikson, 1968). For women, intimacy seems to go along with identity: they come to know themselves through their relationships with others (Gilligan, 1982).

Despite his observation of sex differences, the sequence of stages in Erikson's psychosocial theory remains unchanged (see Table 38.1, page 650). As Gilligan points out:

> Identity continues to precede intimacy as male experience continues to define his [Erikson's] life-cycle concept.

Similarly, Kohlberg's (1969) six-stage theory of moral development was based on a 20-year longitudinal study of 84 boys, but he claims that these stages are universal (see Chapter 35). Females rarely attain a level of moral reasoning above stage three ('Good boy–nice girl' orientation), which is supposed to be achieved by most adolescents and adults. This leaves females looking decidedly morally deficient (*alpha bias*).

Like other feminist psychologists, Gilligan argues that psychology speaks with a 'male voice', describing the world from a male perspective and confusing this with absolute truth (*beta-bias*). The task of feminist psychology is to listen to women and girls who speak in a 'different voice' (Gilligan, 1982; Brown & Gilligan, 1992). Gilligan's work with females has led her to argue that men and women have qualitatively different conceptions of morality. By stressing the *differences* between men and women (an *alpha-biased approach*), Gilligan is attempting to redress the balance, created by Kohlberg's *beta-biased theory.*

ASK YOURSELF...

- In what ways is Freud's psychoanalytic theory (especially the psychosexual stages of development) sexist (or what Grosz, 1987, calls 'phallocentric')?
- Repeat this exercise for Levinson *et al.*'s theory of adult development, and any other theory you're familiar with.

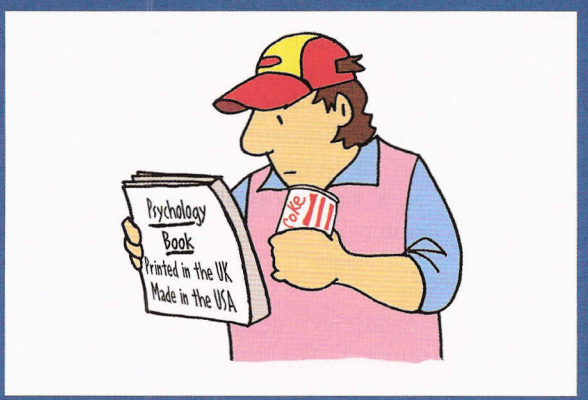
CULTURE BIAS

In discussing gender bias, we've made several references to culture bias. As we noted earlier, Denmark *et al.*'s (1988) report on sexism is meant to apply equally to all other major forms of bias, including cultural (see Box 47.3). Ironically, many feminist critics of Gilligan's ideas have argued that women aren't a cohesive group who speak in a single voice, a view which imposes a false sameness upon the diversity of women's voices across differences of age, ethnicity, (dis)ability, class, and other social divisions (Wilkinson, 1997).

ASK YOURSELF...

- Before reading on, ask yourself what's meant by the term 'culture'.
- How is it related to 'race', 'ethnicity' and 'subcultures'?

Cross-cultural psychology and ethnocentrism



According to Smith & Bond (1998), cross-cultural psychology studies *variability* in behaviour among the various societies and cultural groups around the world. For Jahoda (1978), its additional goal is to identify what's *similar* across different cultures, and thus likely to be our common human heritage (the *universals* of human behaviour).

Cross-cultural psychology is important because it helps to correct *ethnocentrism,* the strong human tendency to use our own ethnic or cultural groups' norms and values to define what's 'natural' and 'correct' for everyone ('reality': Triandis, 1990). Historically, psychology has been dominated by white, middle-class males in the USA. Over the last century, they've enjoyed a monopoly as both the researchers and the 'subjects' of the discipline (Moghaddam & Studer, 1997). They constitute the core of psychology's *First World* (Moghaddam, 1987).

Box 47.4 Psychology's First, Second and Third Worlds

- The USA, the *First World* of psychology, dominates the international arena and monopolises the manufacture of psychological knowledge, which it exports to other countries around the globe, through control over books and journals, test manufacture and distribution, training centres, and so on.
- The *Second World* countries comprise western European nations and Russia. They have far less influence in shaping psychology around the world, although, ironically, it's in these countries that modern psychology has its philosophical roots (see Chapter 3). Just as the countries of the Second World find themselves overpowered by American popular culture, they also find themselves overwhelmed by US-manufactured psychological knowledge.
- *Third World* countries are mostly importers of psychological knowledge, first from the USA but also from the Second World countries with which they historically had colonial ties (such as Pakistan and England). India is the most important Third World 'producer' of psychological knowledge, but even there most research follows the lines established by the USA and, to a lesser extent, western Europe.

(From Moghaddam & Studer, 1997)

According to Moghaddam *et al.* (1993), American researchers and participants:

> ... have shared a lifestyle and value system that differs not only from that of most other people in North America, such as ethnic minorities and women, but also the vast majority of people in the rest of the world.

A symbol of western plenty in the midst of Third World poverty

Yet the findings from this research, and the theories based upon it, have been applied to *people in general,* as if culture makes no difference. An implicit equation is made between 'human being' and 'human being from western culture' (the *Anglocentric* or *Eurocentric bias*).

When members of other cultural groups have been studied, they've usually been *compared* with western samples, using the behaviour and experience of the latter as the 'standard'. As with androcentrism, it's the failure to acknowledge this bias which creates the misleading and false impression that what's being said about behaviour can be generalised without qualification.

Cross-cultural psychologists *don't* equate 'human being' with 'member of western culture', because for them, cultural background is the crucial *independent variable.* In view of the domination of First World psychology, this distinction becomes crucial. At the same time, cross-cultural psychologists consider the search for universal principles of human behaviour as quite valid (and consistent with the 'classical' view of science: see page 856 and Chapter 3).

What is culture?

Herskovits (1955) defines culture as 'the human-made part of the environment'. For Triandis (1994):

> Culture is to society what memory is to individuals. In other words, culture includes the traditions that tell 'what has worked' in the past. It also encompasses the way people have learned to look at their environment and themselves, and their unstated assumptions about the way the world is and the way people should act.

The 'human-made' part of the environment can be broken down into *objective* aspects (such as tools, roads and radio stations) and *subjective* aspects (such as categorisations, associations, norms, roles and values). This allows us to examine how subjective culture influences behaviour (Triandis, 1994). While culture is made by humans, it also helps to 'make' them: humans have an *interactive* relationship with culture (Moghaddam *et al.*, 1993).

Much cross-cultural research is actually based on 'national cultures', often comprising a number of subcultures, which may be demarcated by religion (as in Northern Ireland), language (Belgium), or race (Malaysia and Singapore). However, such research often fails to provide any more details about the participants than the name of the country (national culture) in which the study was carried out. According to Smith & Bond (1998), when this happens, we pay two 'penalties':

- when we compare national cultures, we can lose track of the enormous diversity found within many of the major nations of the world, and differences found between any two countries might well also be found between carefully selected subcultures within those countries;
- there's the danger of implying that national cultures are unitary systems, free of conflict, confusion, and dissent; this is rarely the case.

A multi-racial classroom

How do cultures differ?

Definitions of culture such as those above stress what different cultures have in common. To evaluate research findings and theory that are culturally biased, it's even more important to consider how cultures differ from each other. Triandis (1990) identifies several cultural syndromes, which he defines as:

> ... a pattern of values, attitudes, beliefs, norms and behaviours that can be used to contrast a group of cultures to another group of cultures.

Box 47.5 Three major cultural syndromes used to contrast different cultures

- **Cultural complexity** refers to how much attention people must pay to time. This is related to the number and diversity of the roles that members of the culture typically play. More industrialised and technologically advanced cultures, such as Japan, Sweden and the USA, are more complex in this way.
- **Individualism–collectivism** refers to whether one's identity is defined by personal choices and achievements (the autonomous individual: *individualism*) or by characteristics of the collective group to which one is more or less permanently attached, such as the family, tribal or religious group, or country (*collectivism*). While people in every culture display both, the relative emphasis in the West is towards individualism, and in the East towards collectivism. Broadly, capitalist politico-economic systems are associated with individualism, while socialist societies are associated with collectivism.
- **Tight cultures** expect their members to behave according to clearly defined norms, and there's very little tolerance of deviation from those norms. Japan is a good example of a tight culture, and Thailand an example of a loose culture.

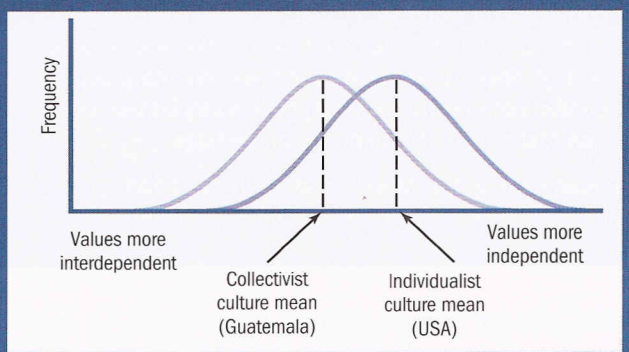


Figure 47.1 Hypothetical distributions of interdependent/independent value scores in a collectivist and an individualist national culture (from Smith & Bond, 1998)

(Based on Smith & Bond, 1998; Triandis, 1990, 1994)

The emic–etic distinction (E-ED)

Research has to begin somewhere and, inevitably, this usually involves an instrument or observational technique rooted in the researcher's own culture (Berry, 1969). These can be used for studying both cross-cultural differences and universal aspects of human behaviour (or the 'psychic unity of mankind').

ASK YOURSELF...

- Try to identify some behaviours (both normal and abnormal) that can be considered to have both universal (common to all cultures) and culture-specific features.

The distinction between culture-specific and universal behaviour is related to what cross-cultural psychologists call the *emic–etic distinction* (E-ED), first made by Pike (1954) to refer to two different approaches to the study of behaviour:

- the *etic* looks at behaviour from *outside* a particular cultural system
- the *emic* looks at behaviour from the *inside*.

This derives from the distinction made in linguistics between phon*etics* (the study of universal sounds, independently of their meaning) and phon*emics* (the study of universal sounds as they contribute to meaning: see Chapter 19).

'Etics' refers to culturally general concepts, which are easier to understand (because they're common to all cultures), while 'emics' refers to culturally specific concepts, which include all the ways that particular cultures deal with etics. It's the emics of another culture that are often so difficult to understand (Brislin, 1993).

The research tools that the 'visiting' psychologist brings from 'home' are an emic for the home culture, but when they're assumed to be valid in the 'alien' culture and are used to compare them, they're said to be an *imposed etic* (Berry, 1969). Many attempts to replicate American studies in other parts of the world involve an imposed etic: they all assume that the situation being studied has the same meaning for members of the alien culture as it does for members of the researcher's own culture (Smith & Bond, 1998).

The danger of imposed etics is that they're likely to involve imposition of the researcher's own cultural biases and theoretical framework. These simply may not 'fit' the phenomena being studied, resulting in their distortion. A related danger is *ethnocentrism*.

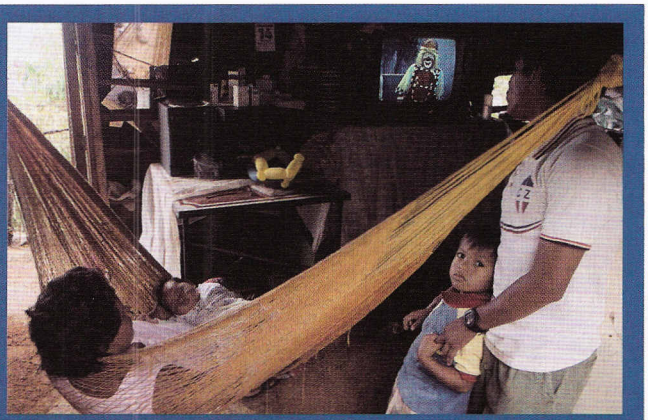
CRITICAL DISCUSSION 47.2 Intelligence as an imposed etic

- Brislin's (1993) example is the concept of intelligence.
- The etic is 'solving problems, the exact form of which hasn't been seen before', a definition which at least recognises that what constitutes a 'problem' differs between cultures.
- However, is the emic of 'mental quickness' (as measured by IQ tests, for example) universally valid?
- Among the Baganda people of Uganda, for example, intelligence is associated with slow, careful, deliberate thought (Wober, 1974). Nor is quick thinking necessarily a valid emic for all schoolchildren within a culturally diverse country like the USA (Brislin, 1993).

ASK YOURSELF...

- Can you identify other examples of imposed etics in relation to intelligence/intelligence tests? (See Chapter 41.)

Village elders in Mali, assembled to make an important decision



Psychologists need to adapt their methods so that they're studying the same processes in different cultures (Moghaddam *et al.*, 1993). But how do we know that we're studying the same processes? What does 'same' mean in this context? For Brislin (1993), this is the problem of *equivalence*. The very experience of participating in psychological testing will be strange and unfamiliar to members of non-western cultures (Lonner, 1990). Even if measures are adapted for use in other cultures, psychologists should be aware that simply being asked to do a test may be odd for some people (Howat, 1999).

Advantages of cross-cultural research

It may now seem obvious (almost 'common sense') to state that psychological theories must be based on the study of people's behaviours from all parts of the world. However, it's important to give specific reasons and examples in support of this argument.

Box 47.6 Major advantages of cross-cultural research (C-CR)

- **Highlighting implicit assumptions:** C-CR allows investigators to examine the influence of their own beliefs and assumptions, revealing how human behaviour cannot be separated from its cultural context.
- **Separating behaviour from context:** Being able to stand back from their own cultural experiences allows researchers to appreciate the impact of situational factors on behaviour. They're thus less likely to make the *fundamental attribution error* (see Chapter 23), or to use a 'deficit model' to explain the performances of minority group members.
- **Extending the range of variables:** C-CR expands the range of variables and concepts that can be explored. For example, people in individualist and collectivist cultures tend to explain behaviour in different ways, with the latter less likely to make dispositional attributions (see Chapter 23).

A researcher would have to go a long way to find a part of the world television hasn't reached

- **Separating variables:** C-CR allows the separation of the effects of variables that may be confounded within a particular culture. For example, studying the effects of TV on school achievement is very difficult using just British or American samples, since the vast majority of these families owns (at least) one TV set!
- **Testing theories:** Only by conducting C-CR can western psychologists be sure whether their theories and research findings are relevant outside their own cultural contexts. For example, Thibaut & Kelley's exchange theory of relationships (see Chapter 28), and Sherif *et al.*'s 'Robber's Cave' field experiment on intergroup conflict (see Key Study 25.1) have all failed the replication test outside North American settings.

(Based on Rogoff & Morelli, 1989; Brislin, 1993; Moghaddam *et al.*, 1993; Smith & Bond, 1998)

Cross-cultural versus cultural psychology

Several criticisms have been made of cross-cultural psychology (CCP), mainly from *cultural psychologists,* for whom mind is embedded in a sociohistorical process that shapes and creates 'multiple realities' (Shweder, 1990). Instead of trying to identify universal 'laws' of psychological functioning (a major goal of CCP: Much, 1995), cultural psychologists adopt a *relativistic* approach and stress the *uniqueness* of different cultures (as in *indigenous* psychology).

CCP is a branch of experimental social, cognitive and personality psychology, and most of what's been known as CCP has presupposed the categories and models derived from (mostly experimental) research with (limited samples of) Euro-American populations. It has mostly either (a) 'tested the hypothesis' or 'validated the instrument' in other cultures, or (b) 'measured' the social and psychological characteristics of members of other cultures with the methods and standards of western populations usually assumed as a valid norm. CCP is an outgrowth of 'mainstream' psychology, with an emphasis on natural scientific methods. The new 'cultural

psychology' (sometimes called *trans*-cultural: e.g. Bruner, 1990; Cole, 1990) can be seen as a rejection of mainstream psychology, favouring the use of qualitative and ethnographic approaches (Martin, 1998).

CONCLUSIONS

Cole (1996) refers to the results of the last 100 years of psychological research (including CCP) as the 'first psychology'. We shouldn't discard these results, since:

> Cross-cultural studies, especially when they are sensitive to the local organization of activity, can serve to refute ethnocentric conclusions that 'those people' suffer from general cognitive deficits as a consequence of cultural inadequacies ...

But Cole advocates a return to the early decades of psychology, particularly Wundt's belief that the methods of natural science could be applied only to the most basic, universal and, therefore, *timeless* aspects of human behaviour. Culturally mediated and historically dependent 'higher psychological processes' need historical and developmental methods. What Wundt was advocating was a:

> ... road along which culture is placed on a level with biology and society in shaping individual human natures. The name correctly given to that enterprise is *cultural psychology,* a major late twentieth-century manifestation of the second psychology ... (Cole, 1996)

Despite its shortcomings, Moghaddam & Studer (1997) believe that CCP is one of the avenues through which minorities have begun to have their voices heard in psychology and that:

> ... there has been a demand that psychology make good its claim to being the science of humankind by including women and non-whites as research participants.

CHAPTER SUMMARY

- A **positivist** study of people implies an objective, value-free psychology, in which the psychologist's characteristics have no influence on the investigation's outcome. However, **sexism** and **ethnocentrism** pervade much psychological theory and research.
- **Feminist psychologists** challenge mainstream psychology's theories about women, who are either excluded from research studies or whose experiences are assimilated to/matched against male norms (**androcentrism**/the **masculinist bias**).
- Male power and social and political oppression are screened out through **individualism**, thus playing down the social context. This reinforces popular gender stereotypes, contributing to women's oppression.
- Feminist psychologists also challenge psychology's claim to be an objective, value-free science. Decisions about what constitutes legitimate research are made by individual scientists within a **sociopolitical context**, making science **ideological**.
- **Scientific method** itself is **gender-biased**, concentrating on the 'subject's' behaviour, rather than its meaning, and ignoring contextual influences. These typically include a male experimenter who controls the situation.
- Using psychometric test results, Wilson argues that men and women differ in terms of mental abilities, motivation, personality, and values, which are based in biology. This demonstrates **alpha bias**.
- According to Denmark *et al.*, gender bias is found at all stages of the **research process.** The last stage (**conclusion formulation**) is related to **theory construction**. Levinson *et al.*'s, Erikson's, and Kohlberg's theories are based on all-male samples and describe the world from male perspectives (**beta bias**).
- **Cross-cultural psychology** (CCP) is concerned with both behavioural **variability** between cultural groups and behavioural **universals**. It also helps to correct **ethnocentrism**.
- American researchers and participants share lifestyles and value systems which differ from those of both most other North Americans and the rest of the world's population. Yet the research findings are applied to people in general, disregarding culture's relevance (the **Anglocentric/Eurocentric bias**).
- **Culture** is the human-made part of the environment, comprising both **objective** and **subjective** aspects. When cross-cultural researchers compare national cultures, they fail to recognise the great diversity often found within them.
- Different cultures can be assessed in terms of **cultural complexity**, **individualism–collectivism**, and considering whether they are **tight** or **loose**. The relative emphasis in the West is towards individualism, and in the East towards collectivism.
- The distinction between culture-specific and universal behaviour corresponds to the **emic–etic distinction** (E-ED). When western psychologists study non-western cultures, they often use research tools which are emic for them but an **imposed etic** for the culture being studied.
- Only by doing cross-cultural research can western psychologists be sure that their theories and research findings are relevant outside their own cultural contexts.
- CCP is an outgrowth of mainstream psychology, adopting a natural scientific approach. **Cultural psychologists** reject this approach in favour of qualitative and ethnographic methods, stressing the **uniqueness** of cultures.

Links with other topics/chapters

- Research into *psychological sex differences* is highly politicised, with a bias towards publishing only those studies that produce significant differences in the expected (i.e. stereotyped) direction (Chapter 36).
- The *pathologising* of homosexuality – and the fact that it's no longer officially a mental disorder – demonstrates how psychiatry (like psychology) isn't objective or value-free (Chapter 44).
- The claim that *scientific enquiry* cannot be neutral isn't made just by feminist psychologists. *Critical psychologists* and *discursive psychologists* (who are sometimes both referred to as 'social constructionists': Burr, 1995; Jones & Elcock, 2001) both reject many of the basic assumptions and practices of mainstream experimental psychology (Chapters 2 and 3).
- Gilligan believes that men and women have different kinds of *morality,* and that Kohlberg's theory is based on a male definition of morality (Chapter 35).
- The concept of time differs between cultures, as reflected in *language* (Chapter 18).
- The tightness of cultures is relevant to the *criteria for defining normality/abnormality* (Chapter 43).

ETHICAL ISSUES IN PSYCHOLOGY

INTRODUCTION AND OVERVIEW

One of psychology's unique features is that people are both the investigators and the subject matter (see Chapter 3). This means that the 'things' studied in a psychological investigation are capable of thoughts and feelings. Biologists and medical researchers share this problem of subjecting living, *sentient* things to sometimes painful, stressful, or strange and unusual experiences in the name of furthering science.

Just as Orne (1962) regards the psychological experiment as primarily a *social situation* (which raises questions of objectivity: see Chapter 3), so every psychological investigation is an *ethical situation* (raising questions of propriety and responsibility). Similarly, just as methodological issues permeate psychological research, so do ethical issues. For example, the aims of psychology as a science (see Chapters 1 and 3) concern what's appropriate as much as what's possible. Social psychology's use of stooges to deceive naïve participants (see Chapters 26, 27, 29 and 30), and the surgical manipulation of animals' brains in physiological psychology (Chapters 4 and 9) are further examples of the essential difference between the study of the physical world and that of living subjects. What psychologists can and cannot do is determined by the effects of the research on those being studied, as much as by what they want to find out.

However, psychologists are practitioners as well as scientists and investigators. They work in practical and clinical settings, where people with psychological problems require help (see Chapters 1 and 45). Whenever the possibility of changing people arises, ethical issues also arise, just as they do in medicine and psychiatry. This chapter looks at the ethical issues faced by psychologists as scientists/investigators, both of humans and non-humans, and as practitioners.

CODES OF CONDUCT AND ETHICAL GUIDELINES

While there are responsibilities and obligations common to both the scientist and practitioner roles, there are also some important differences. These are reflected in the codes of conduct and ethical guidelines published by the major professional bodies for psychologists, the British Psychological Society (BPS) and the American Psychological Association (APA).

As shown in Figure 48.1, *The Code of Conduct for Psychologists* (BPS, 1985) and the *Code of Conduct, Ethical Principles and Guidelines* (BPS, 2000) apply to both the main areas of research and practice, while there are additional documents designed for the two areas separately. The *Ethical Principles for Conducting Research with Human Participants* (BPS, 1990, 1993; now incorporated into the *Code of Conduct,* 2000) and the *Guidelines for the Use of Animals in Research* (BPS and the Committee of the Experimental Psychological Society, 1985) obviously apply to research. The *Code of Conduct* (2000) includes a section on 'Guidelines for psychologists working with animals'. *Guidelines for the Professional Practice of Clinical Psychology* (BPS, 1983) and the *Division of Clinical Psychology Professional Practice Guidelines* (BPS, 1995) both apply to practice.

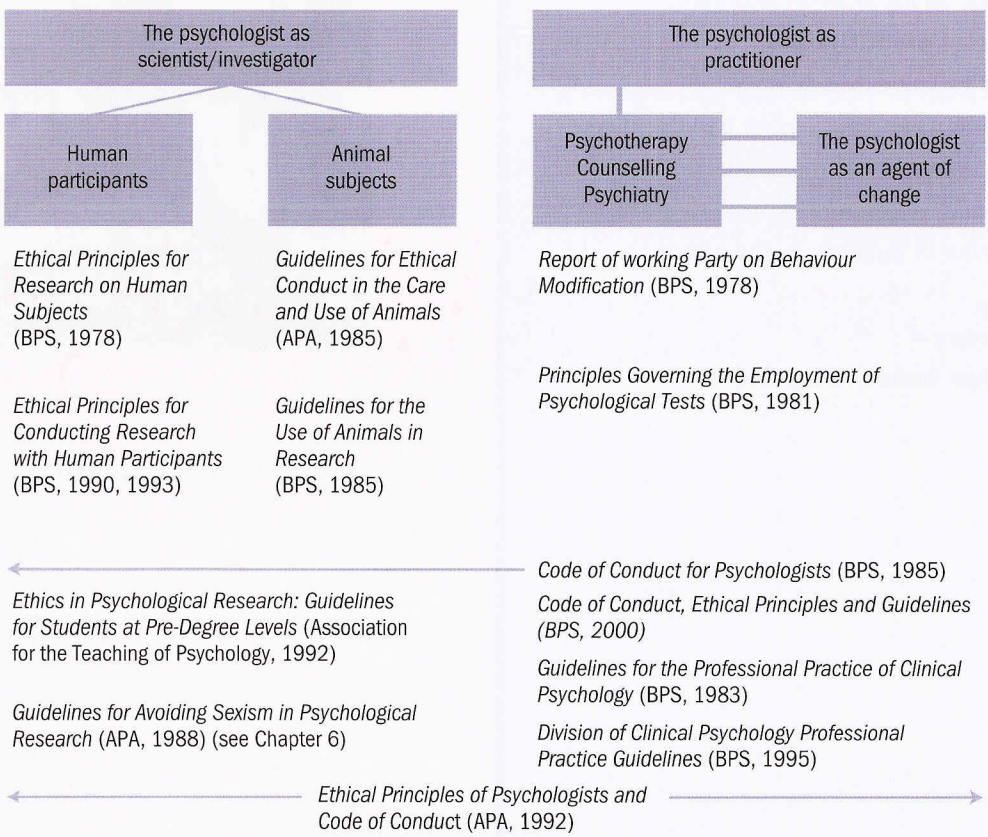

Figure 48.1 Major codes of conduct/ethical guidelines published by the British Psychological Society (BPS) and the American Psychological Association (APA)

ASK YOURSELF...
- Do you think it's necessary for psychologists to have written codes of conduct and ethical guidelines?
- What do you consider to be their major functions?

According to Gale (1995), the fact that both the BPS and APA codes are periodically reviewed and revised indicates that at least some aspects don't depend on absolute or universal ethical truths. Guidelines need to be updated in light of the changing social and political contexts in which psychological research takes place. For example, new issues, such as sexual behaviour in the context of AIDS, might highlight new ethical problems. Information revealed by participants can create conflict between the need to protect individuals and the protection of society at large. For instance, in spite of the confidentiality requirement, should a researcher inform the sexual partner of an HIV-infected participant? (See Critical Discussion 48.2.) As Gale (1995) points out:

> One consequence of such breaches of confidentiality could be the withdrawal of consent by particular groups and the undermining of future research, demonstrating ... how one ethical principle fights against another.

More importantly, changing views about the nature of individual rights will call into question the extent to which psychological research respects or is insensitive to such rights.

One of the earliest formal statements of ethical principles published by the BPS was the *Ethical Principles for Research on Human Subjects* (1978). The *Ethical Principles* (1990, 1993, 2000) refers to 'participants' instead. Gale (1995) believes that this change of wording reflects a genuine shift in how the individual is perceived within psychology, from object (probably a more accurate term than 'subject') to person.

PSYCHOLOGISTS AS SCIENTISTS/INVESTIGATORS

Human participants

The *Ethical Principles for Conducting Research with Human Participants* (BPS, 1990, 1993, 2000, for the rest of this chapter abbreviated to '*Ethical Principles*') identifies several guiding principles. Some of the most important issues addressed are:

- consent/informed consent
- deception
- debriefing
- protection of participants.

The introduction to the *Ethical Principles* states that:

> Psychological investigators are potentially interested in all aspects of human behaviour and conscious experience. However, for ethical reasons, some areas of human experience and behaviour may be beyond the reach of experiment, observation or other forms of psychological investigation. Ethical guidelines are necessary to clarify the conditions under which psychological research is acceptable ... [paragraph 1.2]

Psychologists are urged to encourage their colleagues to adopt the principles and ensure they're followed by all researchers whom they supervise (including GCSE, A/AS level, undergraduate, and postgraduate students):

> In all circumstances, investigators must consider the ethical implications and psychological consequences for the participants in their research. The essential principle is that the investigation should be considered from the standpoint of all participants; foreseeable threats to their psychological well-being, health, values or dignity should be eliminated ... [paragraph 2.1]

Consent and informed consent

According to the *Ethical Principles:*

> Participants should be informed of the objectives of the investigation and all other aspects of the research which might reasonably be expected to influence their willingness to participate – only such information allows informed consent to be given [paragraph 3.1] ... Special care needs to be taken when research is conducted with detained persons (those in prison, psychiatric hospital, etc.), whose ability to give free informed consent may be affected by their special circumstances ... [paragraph 3.5]

ASK YOURSELF...
- You may recall that in Perrin & Spencer's (1981) British replication of Asch's conformity experiment (see Chapter 26, page 446), some of the participants were young offenders on probation, with probation officers as stooges. According to paragraph 3.5, would this be acceptable today?

> Investigators must realise that they often have influence over participants, who may be their students, employees or clients: this relationship must not be allowed to pressurise the participants to take part or remain in the investigation ... [paragraph 3.6]

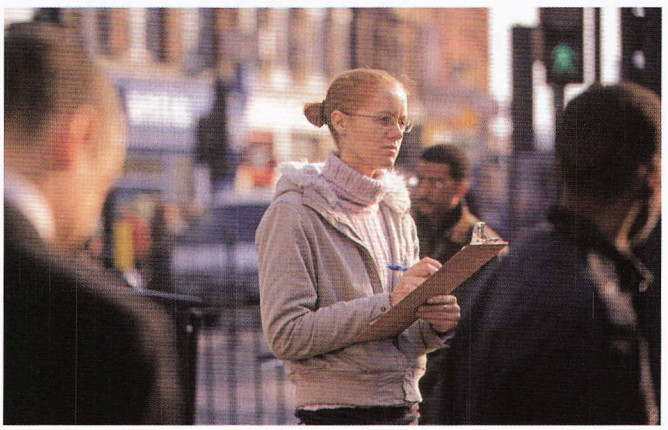
In relation to paragraph 3.6, it's standard practice in American universities for psychology students to participate in research as part of their course requirements. So, while they're free to choose which research to participate in, they're *not* free to opt out altogether.

Box 48.1 Is there more to informed consent than being informed?

- Although informed consent clearly requires being informed of the procedure, participants won't have full

knowledge until they've actually experienced it. Indeed, there's no guarantee that the investigators fully appreciate the procedure without undergoing it themselves.

- In this sense, it's difficult to argue that full prior knowledge can ever be guaranteed. How much information should be given beforehand? How much information can young children, elderly people, infirm or disabled people or those in emotional distress be expected to absorb?
- However, there's more to informed consent than just this 'informational' criterion. The status of the experimenter, the desire to please others and not let them down, the desire not to look foolish by withdrawing after the experiment is already under way, all influence the participant and seem to detract from truly choosing freely in a way that is assumed by the Ethical Principles.



(Based on Gale, 1995)

Deception

The *Ethical Principles* states that:

> Intentional deception of the participants over the purpose and general nature of the investigation should be avoided whenever possible. Participants should never be deliberately misled without extremely strong scientific or medical justification. Even then there should be strict controls and the disinterested approval of independent advisors ... [paragraph 4.2]

The decision that deception is necessary should be taken only after determining that alternative procedures (which avoid deception) are unavailable. Participants must be *debriefed* at the earliest opportunity (see Critical Discussion 48.1).

Observational research: are those being observed giving their consent?

Debriefing

According to Aronson (1988):

> The experimenter must take steps to ensure that subjects leave the experimental situation in a frame of mind that is at least as sound as it was when they entered. This frequently requires post-experimental 'debriefing' procedures that require more time and effort than the main body of the experiment.

Where no undue suffering is experienced, but participants are deceived regarding the real purpose of the experiment:

> The investigator should provide the participant with any necessary information to complete their understanding of the nature of the research. The investigator should discuss with the participants their experience of the research in order to monitor any unforeseen negative effects or misconceptions ... [paragraph 5.1]

However:

> Some effects which may be produced by an experiment will not be negated by a verbal description following the research. Investigators have a responsibility to ensure that participants receive any necessary debriefing in the form of active intervention before they leave the research setting ... [paragraph 5.3]

ASK YOURSELF...

- Active intervention is more like a 'therapeutic' measure than just 'good manners'. Can you give examples of this second type of debriefing from both Milgram's and Zimbardo *et al.*'s experiments? (See Chapter 27.)

Protection of participants

> Investigators have a primary responsibility to protect participants from physical and mental harm during the investigation. Normally, the risk of harm must be no greater than in ordinary life, i.e. participants should not be exposed to risks greater than or additional to those encountered in their normal life styles. [paragraph 8.1]

Debriefing represents a major means of protecting participants where emotional suffering has occurred. They must also be protected from the stress that might be produced by disclosing confidential information without participants' permission. If participants have been seriously deceived, they have the right to witness destruction of any such records they don't wish to be kept. Results are usually made anonymous as early as possible by use of a letter/number instead of name (Coolican, 1994).

Ethical issues arising from the study of social influence

As we noted in Chapter 27, Milgram's obedience experiments have been criticised on ethical grounds, and they're often held up as examples of how psychological research with human participants *shouldn't* be done. They undoubtedly helped highlight the ethical dimension of psychological research, and to define specific principles, such as those discussed above. Milgram's and other experiments in the area of social influence are among the most controversial in the whole of psychology, and for all these reasons are often cited in the context of the ethics of research.

ASK YOURSELF...

- Are there any features of Milgram's experimental procedure that you'd consider unethical?
- One way of approaching this is to ask yourself what you'd have found objectionable/unacceptable, either during or after the experiment, if you'd been one of his participants.

Protection from harm

One of Milgram's fiercest critics was Baumrind (1964), who argued that the rights and feelings of Milgram's participants had been abused, and that inadequate measures had been taken to protect them from stress and emotional conflict. Milgram didn't deny that his participants did experience stress and conflict, but he argued that Baumrind's criticism assumes that the experimental outcome was expected. However, inducing stress *wasn't* an intended and deliberate effect of the experimental procedure. As Milgram (1974) noted:

> Understanding grows because we examine situations in which the end is unknown. An investigator unwilling to accept this degree of risk must give up the idea of scientific enquiry.

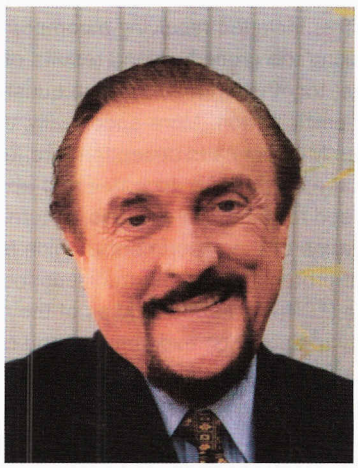
In other words, an experimenter cannot know what the results are going to be before the experiment is conducted.

We might accept Milgram's claim that there was no reason to believe that participants would need protection. However, once he observed the degree of distress in his first experiment, should he have continued with the research programme (17 more experiments)? To justify this, Milgram would have pointed out the following.

- At whatever shock level the experiment ended, the participant was reunited with the unharmed Mr Wallace, and informed that no shock had been delivered. In an extended discussion with Milgram, obedient participants were assured that their behaviour was entirely normal, and that the feelings of conflict and tension were shared by others. Disobedient participants were supported in their decision to disobey the experimenter. This was all part of a thorough debriefing or 'dehoaxing', which happened as a matter of course with every participant (see Critical Discussion 48.1).
- The experimenter didn't *make* the participant shock the learner (as Baumrind had claimed). Milgram began with the belief that every person who came to the laboratory was free to accept or reject the demands of authority. Far from being passive creatures, participants are active, choosing adults.

An APA ethics committee investigated Milgram's research shortly after its first publication in 1963 (during which time Milgram's APA membership was suspended). The committee eventually judged it to be ethically acceptable (Colman, 1987). In 1965, Milgram was awarded the prize for outstanding contribution to social psychological research by the American Association for the Advancement of Science.

According to Zimbardo (1973), the ethical concerns are even more pronounced in his own prison simulation experiment (see Chapter 27) than in Milgram's experiments:



> Volunteer prisoners suffered physical and psychological abuse hour after hour for days, while volunteer guards were exposed to the new self-knowledge that they enjoyed being powerful and had abused this power to make other human beings suffer. The intensity and duration of this suffering uniquely qualify the Stanford prison experiment for careful scrutiny of violations of the ethics of human experimentation.

Savin (1973) argued that the benefits resulting from Zimbardo *et al.*'s experiment didn't justify the distress, mistreatment and degradation suffered by the participants – the end didn't justify the means.

ASK YOURSELF...

- How could Zimbardo *et al.* defend themselves against this criticism in a way that Milgram couldn't?

Their experiment was due to last for two weeks, but when it was realised just how intense and serious the distress, mistreatment and degradation were, it was ended after six days. However, it could be asked why it wasn't stopped even sooner!

Philip Zimbardo (born 1933)

Deception and informed consent

According to Vitelli (1988), almost all conformity and obedience experiments (and more than one-third of all social psychological studies) deceive participants over the purpose of the research, the accuracy of the information they're given, and/or the true identity of a person they

believe to be another genuine participant (or experimenter). Deception is considered unethical for two main reasons:

- it prevents the participant from giving informed consent – that is, agreeing to participate knowing the true purpose of the study and what participation will involve
- the most potentially harmful deception is involved in studies, like those of Milgram and Zimbardo *et al.*, in which participants learn (unsettling) things about themselves as people.

ASK YOURSELF...

- Given that it's important to understand the processes involved in conformity and obedience (the end), can deception be justified as a means of studying them?
- Identify the deceptions that were involved in the experiments of Asch (see Chapter 26), Milgram and Zimbardo *et al.*
- Do you consider any of these to be more serious/unethical than the others, and if so, why?

CRITICAL DISCUSSION 48.1 Can deception ever be justified?

- Most participants deceived in Asch's conformity experiments were very enthusiastic, and expressed their admiration for the elegance and significance of the experimental procedure (Milgram, 1992).
- In defence of his own obedience experiments, Milgram (1974) reported that his participants were all thoroughly debriefed. This included receiving a comprehensive report detailing the procedure and results of all the experiments, together with a follow-up questionnaire about their participation. More specifically, the 'technical illusions' (as Milgram calls deception) are justified because in the end they're accepted and approved of by those exposed to them. He saw this, in turn, as justifying the *continuation* of the experiments, which is relevant to the issue of protection from harm discussed above.
- Christensen (1988) reviewed studies of the ethical acceptability of deception experiments and concluded that as long as deception isn't extreme, participants don't seem to mind. Christensen suggests that the widespread use of mild forms of deception is justified, first because no one is apparently harmed, and second, because there seem to be few, if any, acceptable alternatives.
- Krupat & Garonzik (1994) reported that university psychology students who'd been deceived at least once as research participants didn't find the experience less enjoyable or interesting as a result. They also said they'd be less upset if they were lied to or misled again in the future (compared with those who hadn't been deceived).
- Other researchers have defended Milgram's use of deception on the grounds that without it, he'd have found results which simply don't reflect how people behave when they're led to believe they're in real situations (Aronson, 1988). In some circumstances, then, deception may be the best (and perhaps the only) way to obtain useful information about how people behave in complex and important situations.

As far as Zimbardo *et al.*'s prison simulation study is concerned, the only deception involved surrounded the arrest of the prisoners at the start of the experiment. They weren't told this would happen, partly because final approval from the local police force wasn't given until minutes before they decided to participate, and partly because the researchers wanted the arrests to come as a surprise.

As Zimbardo (1973) admits, 'This was a breach, by omission, of the ethics of our own informed consent contract', which told participants of everything that was going to happen to them (as far as this could be predicted). It was signed by every one of them, thus giving their permission for invasion of privacy, loss of civil rights, and harassment. Approval for the study had also been officially sought and received, in writing, from the body that sponsored the research, the Psychology Department at Stanford University, and the University Committee of Human Experimentation. This Committee didn't anticipate the extreme reactions that were to follow.

Like Milgram, Zimbardo *et al.* held debriefing sessions (both group and individual). All participants returned post-experimental questionnaires several weeks, then several months, later, then at yearly intervals. Many submitted retrospective diaries and personal analyses of the effects of their participation:

> We are sufficiently convinced that the suffering we observed, and were responsible for, was stimulus bound and did not extend beyond the confines of that basement prison ... (Zimbardo, 1973)

Widening the ethical debate: the ethics of socially sensitive research (SSR)

What is SSR?

According to Sieber & Stanley (1988), SSR refers to:

> ... studies in which there are potential social consequences or implications, either directly for the participants in the research or for the class of individuals represented by the research ...

Two examples they give are:

1. a study that examines the relative merits of daycare for infants versus full-time care by the mother can have broad social implications, and thus can be regarded as socially sensitive (see Chapter 32)

2. studies aimed at examining the relationship between gender and mathematical ability, which can also have significant social implications (see Chapter 47).

Sieber (2004) gives the further examples of domestic violence and teenagers and smoking. In research on domestic violence, the victim may experience severe distress at recounting being battered. The assailant may learn of the research and, in anger, harm the participant or the researcher – or the data may be subpoenaed in an investigation of the assailant. Most teenagers smoke without their parents' knowledge, yet research involving minors (usually under 16) should be done with parental permission.

Smoking teenagers: what should investigators do?

The American Psychological Association's (APA) *Ethical Principles in The Conduct of Research* (1982) acknowledges the social implications of research as follows:

> The scientific enterprise creates ethical dilemmas. Scientific knowledge and techniques that can be used for human betterment can be turned to manipulative and exploitative purposes as well. Just as results of research in atomic physics can be used for the treatment of cancer as well as for destructive weapons, so methods discovered to reduce prejudice towards minority groups, to eliminate troublesome behaviour problems, or to facilitate learning in school may also be used to manipulate political allegiance, to create artificial wants, or to reconcile the victims of social injustice to their fate ...

In other words, psychological research (like other scientific research) is a 'double-edged sword'. It can be used to benefit those being studied, or against their interests and for the benefit of those with social, economic and political power. There's nothing 'neutral' about research (see above and Chapters 3 and 47).

Protecting the individual versus harming the group

The debate about the ethics of psychological research usually focuses on the vulnerability of individual participants and the responsibility of psychologists to ensure they don't suffer in any way from their participation. 'Protection of participants' is one of the specific principles included in the *Ethical Principles,* but the principles *as a whole* are designed to prevent any harm coming to the participant, or the avoidance of overt 'sins' (Brown, 1997).

Sometimes the principles designed to protect individual participants can throw up problems and dilemmas for the researcher. This is especially likely in the case of SSR (and could even be considered a defining feature of SSR). Confidentiality is an example, and is described in Box 48.2 in relation to AIDS.

Box 48.2 Protecting the individual versus protecting society

- An example of SSR where the conduct of research and the treatment of participants can cause ethical dilemmas is investigation of patterns of transmission of AIDS.
- The way in which appropriate research groups are identified (such as waiting outside gay bars) can breach *privacy needs.*
- *Confidentiality* can also be a major problem. If a participant reveals that s/he has AIDS, continues to have unprotected sex and withholds the fact that s/he has AIDS from partners, what is the appropriate role of the researcher? Should they maintain the promise of confidentiality, reveal the information to the authorities or try to contact the participant's partner(s) directly (Sieber & Stanley, 1988)?
- Melton & Gray (1988) make a strong general case for tipping the balance towards respecting the confidentiality rights of the participant. Ultimately, this approach will protect the integrity of data collected by future researchers. In other words, if individuals from a relatively cohesive research population (such as gay men/lesbians) become aware of breaches of confidentiality, this is likely to be conveyed to other members of their group. As a result, they'll be less willing to participate in other studies or to give truthful information if they do.

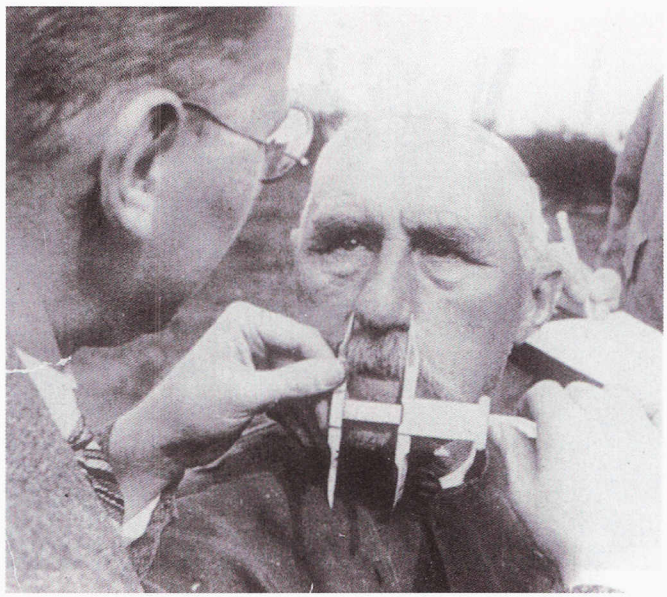
Brown (1997) argues that formal codes focus too narrowly on risks to the individual participant, in the specific context of the investigation. They neglect broader questions about the risks to the *group* the participant belongs to. These groups can include women, ethnic minorities and other subcultural groups, as well as non-western cultures (countries or national cultures). So the different examples of gender and culture bias (see Chapter 47) become relevant to a discussion of ethics. To the extent that these biases (and the underlying values and beliefs) are harmful to particular groups, they are ethical issues. In this sense, any comparison between

women and men that is made from an alpha bias perspective is *socially sensitive*. Equally, any comparison between blacks and whites is socially sensitive. A much-debated example is the study of racial differences in IQ (see below).

ASK YOURSELF...

- Re-read Chapter 47. Try to identify some fundamental values and biases that are potentially damaging to particular social groups.
- In what ways are these values/biases harmful to these groups?

CRITICAL DISCUSSION 48.2 The ethics of ethical codes: underlying assumptions



- According to Brown (1997), a core assumption underlying ethical codes is that what psychologists do as researchers, clinicians, teachers, and so on, is basically harmless and inherently valuable, because it's based on 'science' (defined as positivism: see Chapter 3). Consequently, it's possible for a psychologist to conduct technically ethical research but still do great harm. For example, a researcher can adhere strictly to 'scientific' research methodologies, get technically adequate informed consent from participants (and not breach any of the other major prescribed principles), but still conduct research that claims to show the inferiority of a particular group. Because it's conducted according to 'the rules' (both methodological and ethical), the question of whether it's ethical in the broader sense to pursue such matters is ignored.
- For example, neither Jensen (1969) nor Herrnstein (1971) was ever considered by mainstream psychology to have violated psychology's ethics by the questions they asked regarding the intellectual inferiority of African-Americans (see Chapter 41). Individual black participants weren't harmed by being given IQ tests, and may even have found them interesting and challenging.
- However, Brown (1997) argues that the way the findings were interpreted and used:

  ... weakened the available social supports for people of colour by stigmatising them as genetically inferior, thus strengthening the larger culture's racist attitudes. Research ethics as currently construed by mainstream ethics codes do not require researchers to put the potential for this sort of risk into their informed consent documents ...

- Jensen's and Herrnstein's research (highlighted by Herrnstein and Murray, in *The Bell Curve,* 1994) has profoundly harmed black Americans. Ironically, the book has received much methodological criticism, but only black psychologists (such as Hilliard, 1995, and Sue, 1995) have raised the more fundamental question of whether simply conducting such studies might be ethically dubious. As Brown observes:

  To ask this question about the risks of certain types of inquiry challenges science's hegemony as the source of all good in psychology.

- Herrnstein and Murray, Rushton (1995), Brand (cited in Richards, 1996a) and others, like the Nazi scientists of the 1930s, claim that the study of race differences is a purely 'objective' and 'scientific' enterprise (Howe, 1997).

Nazi scientist conducting 'objective' scientific research

So, psychologists might believe that (a) it's unethical to deceive individual black or female participants about the purposes of some particular study, but (b) it's ethically acceptable to use the results to support the claim that blacks or women are genetically inferior. This narrow view of ethics makes it an ineffective way of guiding research into socially sensitive issues (Howitt, 1991). Formal codes continue to focus narrowly on risks to the individual participant, in the specific context of the investigation, but neglect questions about the risks to the group to which the participant belongs:

As long as research ethics avoid the matter of whether certain questions ethically cannot be asked, psychologists will conduct technically ethical research that violates a more general ethic of avoiding harm to vulnerable populations ... (Brown, 1997)

The BPS *Code of Conduct* (2000) comprises several sections (apart from the *Ethical Principles*). These include (a) 'Guidelines for psychologists working with animals' (see below), (b) 'Guidelines on advertising the services

offered by psychologists', and (c) 'Guidelines for penile plethysmography (PPG) usage'. The last of these refers to the measurement of sexual arousal and involves apparatus being attached to the penis and sexual stimuli being presented. This might be used in the context of assessing paedophilia and sexual dysfunction – so its use is highly sensitive.

Protecting the individual versus benefiting society

As we've seen, the questions psychologists ask are limited and shaped by the values and biases of individual researchers. We've also seen that the research they carry out is constrained by ethical considerations. But it's also constrained by considerations of methodology (what it's possible to do, practically, when investigating human behaviour and experience). For example, in the context of intimate relationships, the laboratory experiment is, by its very nature, extremely limited in the kinds of questions it allows psychologists to investigate (Brehm, 1992: see Chapter 28).

Conversely, and just as importantly, there are certain aspects of behaviour and experience that could be studied experimentally, although it would be unethical to do so (such as jealousy between partners). As Brehm says:

> All types of research in this area involve important ethical dilemmas. Even if all we do is to ask subjects to fill out questionnaires describing their relationships, we need to think carefully about how this research experience might affect them and their partner.

So, what it may be *possible* to do may be *unacceptable,* but equally, what may be *acceptable* may *not* be possible. As we saw earlier, focusing on protection of individual participants can work to the detriment of whole groups. But, by the same token, it may discourage psychologists from carrying out *socially meaningful* research (what Brehm, 1992, calls the *ethical imperative*) which may, potentially, improve the quality of people's lives. Social psychologists in particular have a two-fold ethical obligation, to individual participants and to society at large (Myers, 1994). This relates to discussion of psychology's aims as a science (see Chapters 1 and 3). Similarly, Aronson (1992) argues that social psychologists are:

> ... obligated to use their research skills to advance our knowledge and understanding of human behaviour for the ultimate aim of human betterment. In short, social psychologists have an ethical responsibility to the society as a whole.

ASK YOURSELF...

- Before reading on, try to think of some examples of how research findings you're familiar with might be used to benefit people in general. You may find it useful to focus on social psychology.

Box 48.3 An example of the benefits of social psychological research

- In many bystander intervention studies (e.g. Latané & Darley, 1968: see Chapter 30), people are deceived into believing that an 'emergency' is taking place. Many of Latané and Darley's participants were very distressed by their experiences, especially those in the experiment in which they believed another participant was having an epileptic fit. Yet when asked to complete a post-experimental questionnaire (which followed a very careful debriefing), all said they believed the deception was justified and would be willing to participate in similar experiments again. None reported any feelings of anger towards the experimenter.
- Beaman *et al.* (1978) built on these earlier experiments. They used a lecture to inform students about how other bystanders' refusals to help can influence both one's own interpretation of an emergency and feelings of responsibility.
- Two other groups of students heard either a different lecture or no lecture at all. Two weeks later, as part of a different experiment in a different location, the participants found themselves (accompanied by an unresponsive stooge) walking past someone who was slumped over or sprawled under a bike. Of those who'd heard the lecture about helping behaviour, 50 per cent stopped to offer help compared with 25 per cent who hadn't.
- This suggests that the results of psychological research can be used to make us more aware of influences on behaviour, making it more likely that we'll act differently armed with that knowledge from how we might otherwise have done. In the case of bystander intervention, this 'consciousness-raising' is beneficial in a tangible way to the person who's helped. Being more sensitive to the needs of others, and feeling satisfied with having helped another person, may also be seen as beneficial to the helper.

The 'double obligation dilemma' (DOD)

The dilemma faced by social psychologists (regarding their obligations to society and individual participants) is greatest when investigating important areas such as conformity, obedience and bystander intervention (Aronson, 1992). In general, the more important the issue, (i) the greater the potential benefit for society, and (ii) the more likely an individual participant is to experience distress and discomfort. This is because the more important the issue, the more essential the use of *deception* becomes (see above).

Psychologists want to know how people are likely to behave if they found themselves in that situation *outside* the laboratory. This raises several crucial methodological questions. But the key *ethical* issue hinges on the fact that the use of deception (a) contributes enormously (and perhaps irreplaceably) to our understanding of human

behaviour (helping to satisfy the obligation to society), and at the same time (b) significantly increases individual participants' distress (detracting from the responsibility to protect individuals).

According to Sieber & Stanley (1988):

> The likelihood that psychological research will raise socially sensitive issues is great and often unavoidable if useful theory, knowledge, and applications are to be achieved. Restricting psychology to those areas unlikely to raise socially sensitive issues may limit researchers in psychology to examining relatively unimportant problems.

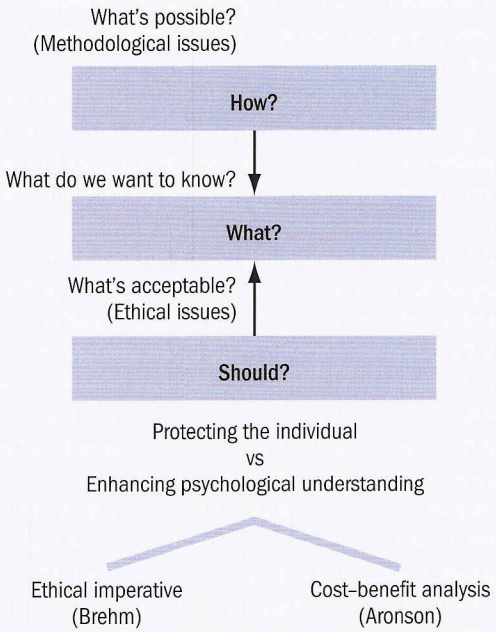


Figure 48.2 Ethical and methodological constraints on the questions that psychologists can try to answer through the research process

'Socially important' and 'socially sensitive' seem to go together, two sides of a coin. Psychologists are obliged to confront the ethical issues raised by SSR. But equally, as Sieber and Stanley say:

> ... shying away from controversial topics, simply because they are controversial, is also an avoidance of responsibility.

Similarly, Milgram (1992) believes that if the experimental creation of stress or conflict were excluded on principle, and only studies that produced positive emotions were allowed, this would produce:

> ... a very lopsided psychology, one that caricatured rather than accurately reflected human experience.

Box 48.4 Some proposed solutions to the 'double obligation dilemma'

- Having accepted that, under certain circumstances, deception is permissible, most psychologists still advocate that it shouldn't be used unless it's considered essential (Milgram, 1992; Aronson, 1992). This is consistent with the *Ethical Principles*.
- Aronson (1992) advocates a *cost–benefit analysis* (CBA): weighing how much 'good' (benefits to society) will derive from doing the research against how much 'bad' will happen to the participants (but see Critical Discussion 48.3).
- Two compromise solutions to the problem of not being able to obtain informed consent are *presumptive consent* (of 'reasonable people') and *prior general consent*.
- In *presumptive consent*, the views of many people are obtained about an experimental procedure's acceptability. These people wouldn't participate in the actual experiment (if it went ahead), but their views could be taken as evidence of how people in general would react to participation.
- *Prior general consent* could be obtained from people who might, subsequently, serve as experimental participants. Before volunteering to join a pool of research volunteers, people would be explicitly told that sometimes participants are misinformed about a study's true purpose and sometimes experience emotional stress. Only those agreeing would be chosen (Milgram, 1992). This is a compromise solution, because people would be giving their 'informed consent' (a) well in advance of the actual study, (b) only in a very general way, and (c) without knowing what specific manipulations/deceptions will be used in the particular experiment in which they participate. It seems to fall somewhere between 'mere' consent and full 'informed consent' (and could be called *semi- or partially informed consent*).

CRITICAL DISCUSSION 48.3 Some problems with cost–benefit analysis (McGhee, 2001)

- Both costs and benefits are multiple and subjective, some are immediate, others are longer-term, and there are difficulties in 'adding them up'.
- Every psychology experiment (like every complex social activity) has multiple outcomes. It's difficult, if not impossible, to identify them, let alone assess them. Even if they can be assessed individually, they need to be aggregated in some way, because we're trying to assess the experiment as an overall package. For example, how much is deception 'worth' relative to the 'new data'?
- Ultimately, costs and benefits can only be subjectively assessed. Each individual values different kinds of experiences (gains and losses) differently. Indeed, one person's cost might be another's benefit.
- In theory-driven research such as Milgram's (as opposed to applied research), costs tend to be real, while benefits tend to be potential.

The distress to the participants in Milgram's studies is real but the prospect of reducing the possibility of another Auschwitz is remote – even if extraordinarily desirable.

- Similarly, although the benefits may outweigh the costs, for individual participants it's mostly all costs (time, effort, stress, and occasional humiliation and deception). Any tangible or practical benefits are unlikely to be for them. So, the costs are linked to specific people, while the identity of those who will benefit is much less obvious.
- We need to decide before a study takes place whether or not it should go ahead, but very often the full range and extent of costs and benefits will only become apparent retrospectively.
- Finally, who should have the right to decide whether the benefits outweigh the costs?

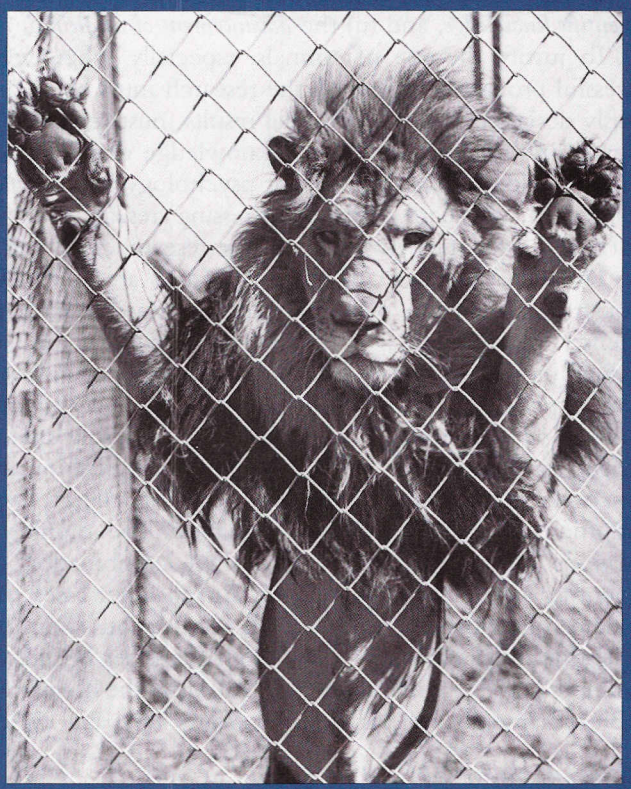
Non-human (animal) subjects

The BPS Scientific Affairs Board published its *Guidelines for the Use of Animals in Research* (1985), in conjunction with the Committee of the Experimental Psychological Society. (The *Guidelines* published in 2000 are an updated version of the 1985 document.) It offers a checklist of points which investigators should carefully consider when planning experiments with living non-humans. Researchers have a general obligation to:

> ... avoid, or at least to minimise, discomfort to living animals ... discuss any future research with their local Home Office Inspector and colleagues who are experts in the topic ... seek ... widespread advice as to whether the likely scientific contribution of the work ... justifies the use of living animals, and whether the scientific point they wish to make may not be made without the use of living animals ... (BPS, 1985)

These warnings raise two fundamental questions: (a) how do we know non-humans suffer, and (b) what goals can ever justify subjecting them to pain, suffering and even death?

How do we know that animals suffer?

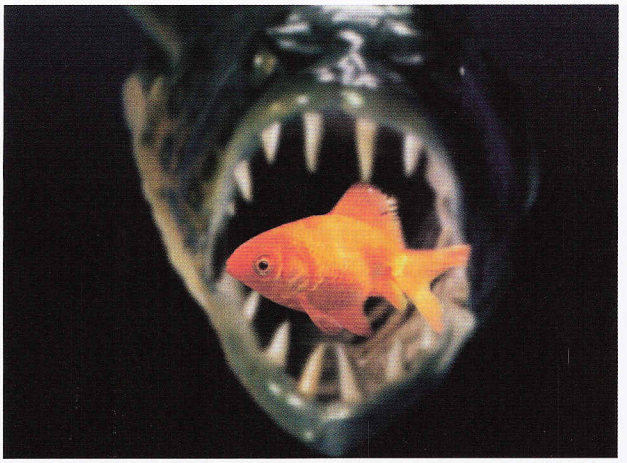


ASK YOURSELF...

- Identify examples of experiments involving animals in which they suffered pain and distress.
- Try to specify in what ways suffering occurred.

Box 48.5 Some criteria for judging animal suffering

- Disease and injury are generally recognised as major causes of suffering. Consequently, research such as Brady's (1958) 'executive monkey' experiments would probably not even be debated in the current climate (Mapstone, 1991). Brady attached pairs of monkeys to an apparatus which gave electric shocks, such that one monkey (the 'executive': see Chapter opening) could prevent the shock by pressing a lever, but the other couldn't. The former developed ulcers and eventually died.
- Even if we're sure that animals aren't suffering physically, their confinement might cause mental suffering not affecting their external condition (Dawkins, 1980). For example, apparently healthy zoo and farm animals often show bizarre behaviours.
- We must find out about animal suffering by careful observation and experimentation. Because different species have different requirements, lifestyles, and, perhaps, emotions, we cannot assume that we know about their suffering or wellbeing without studying them species by species (Dawkins, 1980).
- Drawing on the Institute of Medical Ethics (IME) Working Party's report (Haworth, 1992), Bateson (1986, 1992) has proposed criteria for assessing animal suffering, including:
  (a) possessing receptors sensitive to noxious or painful stimulation, and
  (b) having brain structures comparable to the human cerebral cortex.



Bateson (1992) tentatively concludes that insects probably don't experience pain, whereas fish and octopi probably do. However, the boundaries between the presence and absence of pain are 'fuzzy'.

A caged lion 'climbing the walls'

ASK YOURSELF...

- Try to formulate arguments for and against the use of animals in research.
- This shouldn't be confined to psychological research, since much of the debate takes place in relation to medicine, pharmacology, and so on.

Is the unsuspecting goldfish going to feel pain?

How can we justify experiments with non-humans?

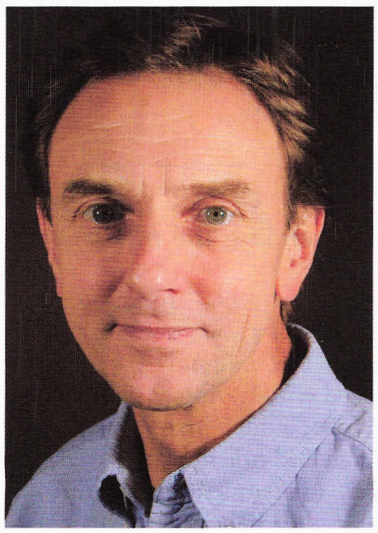
The question of whether or not animals suffer wouldn't arise if animals weren't being used in experiments in the first place. According to Gray (1987), the main justifications for animal experimentation are (i) the *pursuit of scientific knowledge,* and (ii) the *advancement of medicine.*

To justify the use of animals, especially when very stressful procedures are used, the research must be rigorously designed and the potential results must represent a significant contribution to our knowledge of medicine, pharmacology, biopsychology, or psychology as a whole. This is a safeguard against distressing research being carried out for its own sake, or at the researcher's whim.

The *Guidelines* state that if the animals are confined, constrained, harmed, or stressed in any way, the experimenter must consider whether the knowledge to be gained justifies the procedure. Some knowledge is trivial, and experiments mustn't be done simply because it's possible to do them. To take the executive monkey experiments again (see Box 48.5), the medical justification (to discover why business executives develop ulcers) was insufficient to justify their continuation. The monkeys' obvious suffering superseded even the combination of scientific and medical justification. But in other cases, the medical justification may be much less obvious than the scientific justification. An example of the latter is Olds & Milner's (1954) electrical self-stimulation of the brain/ES-SB experiments with rats (see Key Study 9.5, page 150).

Safeguards for animal subjects

Whatever practical application Olds and Milner's ES-SB experiments may have subsequently had (such as pain/anxiety relief in psychotics, epileptics and cancer patients), they don't seem to have been conducted with such human applications in mind. Can the scientific knowledge gained about ES-SB as a very powerful positive reinforcer on its own justify the rats' eventual 'sacrifice'? The very least required of researchers is that the minimum of suffering is caused, both during and following any surgical procedure and by any electric shock or food deprivation, the most objected-to treatments (Gray, 1987).



Box 48.6 Some safeguards for animal subjects

- Gray (1987) claims that food deprivation isn't a source of suffering, and that rats (the most commonly used experimental subjects in psychology) are either fed once a day when experimentation is over, or maintained at 85 per cent of their free-feeding (*ad lib*) body weight. Both are actually healthier than allowing them to eat ad lib.
- Electric shock may cause *some* but not extreme pain (based on observations of the animals' behaviour). The level permitted is controlled by the Home Office (HO) inspectors, who monitor implementation of The Animals (Scientific Procedures) Act (1986). The average level used in the UK is 0.68 milli-amperes, for an average of 0.57 seconds. This produces an unpleasant tickling sensation in humans.
- Procedures causing pain or distress are illegal, unless the experimenter holds an HO licence and relevant certificates. Even then, these procedures should be carried out only if there are no alternative ways of conducting the experiment. Similarly, it's illegal in the UK to perform any surgical or pharmacological procedure on vertebrates (or one invertebrate – the octopus) without an HO licence and relevant certification. Such procedures must be performed by experienced personnel.
- The *Guidelines* stress the importance of understanding species differences in relation to (i) caging and social environment, (ii) the stress involved in marking wild animals for identification or attaching them with radio transmitters, and (iii) the duration of food/drink deprivation. Field workers should disturb non-humans as little as possible. Even simple observation of animals in the wild can have marked effects on their breeding and survival.
- The number of animals used in laboratory experiments is declining. For example, in the UK, the Netherlands, Germany and several other European countries, the numbers have fallen by half since the 1970s (Mukerjee, 1997). However, the UK still used 2.73 million animals in 2002 (84 per cent of which were mice, rats and other rodents) and is the largest user in the European Union (Brown, 2004). There's also been a sharp rise in genome-related research, which is threatening to reverse this downward trend (Hawkes, 2000b). But putting this in perspective, over 700 million non-humans are killed for food every year (*Nursing Times*, 1996).
- The UK, Australia, Germany and several other countries require a utilitarian *cost–benefit analysis* to be performed before any animal experiment can proceed (Mukerjee, 1997; Rowan, 1997). This involves weighing up animal pain, distress, and death against acquisition of new knowledge and the development of new medical therapies for humans. Interestingly, most non-scientists also seem to perform some kind of cost-benefit analysis (Aldhous *et al.*, 1999: see Critical Discussion 48.4).

Despite these safeguards, the very existence of the 1986 Act condones the use of animals. Legally, the Act aims to spare animals 'unnecessary' pain and distress; implicitly, the law accepts that some research will involve suffering for the non-human subjects. Under the Act, applications for project licences have to say whether they've considered alternatives to using non-humans, and in granting the licence the Home Secretary must weigh up the likely benefit of the research against the adverse effects on the animal subjects. However, there's no remit to consider whether the proposed research is truly necessary (Seymour, 1996). Also, the Medicines Act (1968) requires that all new medicines undergo a range of tests on animals before they can be tested on humans (Lyall, 1993: see Critical Discussion 48.4).

A list of 110 British scientists has called for the Home Office to speed up the process of gaining approval for animal experiments: their complaint is that the procedure is so long-winded that foreign scientists will take all the prizes for medicine, biotechnology and drug research (Hawkes, 2000a). The list includes Blakemore (see Chapter 16), Gray (see below), Greenfield (see Chapters 7 and 8), and Iversen (see Chapter 4).

The *Guidelines for Psychologists Working with Animals* (BPS, 2000) point out that research isn't the only reason psychologists work with animals (though, not surprisingly, research is what has caused the most controversy and media attention). Animals are sometimes used in practical teaching within psychology degree courses, and increasingly they're being used in various forms of psychological therapy. The latter includes companion animal visiting schemes in hospitals or hospices, pet-keeping within prison rehabilitation schemes, and in behaviour therapy for the treatment of specific animal phobias. Psychologists may also be asked for advice on therapy for animals whose behaviour is disordered or inconvenient, and in training animals for commercial purposes (such as appearing in TV commercials).

Colin Blakemore (born 1944)

The *Guidelines* state that in all these non-research situations:

> ... considerations concerning the general care and welfare of therapeutic animals are similar to those ... for experimental animals. In addition, however, a number of specific considerations can be noted ...

These include issues relating to the temperament and training of the animals, and their need for protection and rest.

Kirby, a Pet Assisted Therapy (PAT programme) dog, visiting hospital patients in Los Angeles, California

The medical justification argument

The strongest argument for animal experiments is undoubtedly the advancement of medical knowledge and treatments. However, scientific and ethical issues can easily become confused. Showing what's been achieved in a practical sense from such experiments represents only a *minimum requirement* for their justification. For example, only if it can be convincingly shown that many drugs used in the treatment of human diseases (including anti-cancer drugs, AIDS treatments, anti-epileptic and antidepressant drugs) have been developed using animals – and couldn't have been developed otherwise – can the ethical debate begin.

CRITICAL DISCUSSION 48.4 Are animal experiments scientifically useful?

The case for

- Animal experiments have played a crucial role in the development of modern medical treatments, and will continue to be necessary as researchers seek to alleviate existing ailments and respond to the emergence of new diseases.
- The causes of, and vaccines for, dozens of infectious diseases, including diphtheria, tetanus, rabies, whooping cough, tuberculosis, poliomyelitis, measles, mumps, and

rubella, have been determined largely through animal experimentation. It's also led to the development of antibacterial and antibiotic drugs.
- Animal research has also been vital to areas of medicine such as open-heart surgery, kidney disease, organ transplantation, diabetes, malignant hypertension, and gastric ulcers.
- There are no basic differences between the physiologies of laboratory animals and humans. Both control their internal biochemistry by releasing the same basic endocrine hormones, both send out similar chemical transmitters from neurons in the CNS and PNS (see Chapter 4), and both react in the same way to infection or tissue injury. Animal models of disease (see below) are intended to provide a means of studying a particular procedure (such as gene therapy for cystic fibrosis).

The case against

- Through genetic manipulation, surgical intervention or injection of foreign substances, researchers produce diseases in laboratory animals that 'model' human diseases. However, evolutionary pressures have produced innumerable subtle differences between species, and the knock-on effect of applying a stimulus to one particular organ system on the animal's overall physiological functioning is often unpredictable and not fully understood.
- Important medical advances have been delayed because of misleading results from animal experiments. Cancer research is especially sensitive to physiological differences between species. Rats and mice, for example, synthesise about 100 times the recommended daily allowance of vitamin C believed to help the (human) body ward off cancer. Penicillin is toxic to guinea-pigs, while morphine stimulates cats (the opposite of the human response).
- The stress of handling, confinement, and isolation alters an animal's physiology, introducing a variable that makes extrapolating results to humans even more difficult. Laboratory stress can increase animals' susceptibility to infectious disease and certain tumours, as well as influencing hormone and antibody levels.
- Animal experiments to test the safety of drugs are confounded by the fact that tests on different species often produce conflicting results.

(Based on Barnard & Kaufman, 1997; Botting & Morrison, 1997; Mukerjee, 1997; Sawyer, 1996)

Green (1994), Carlson (1992), and many other biopsychologists believe that the potential benefits of animal experiments is sufficient to justify their use.

ASK YOURSELF...

- What do you think of the claim that particular non-human species, namely those that are closest to us in an evolutionary sense, should be given 'special consideration' in the context of animal experiments?

CRITICAL DISCUSSION 48.5 Chimpanzees, AIDS and moral responsibility

- What will become of several hundred research 'veterans' that are now considered to be of no further value to medical science? Their plight is a direct consequence of their genetic similarity to human beings, which makes them ideal models for the study of several diseases afflicting people worldwide, and the quest to find vaccines against them.
- During the 1970s, chimpanzees started to be used in large numbers in biomedical research in the USA. This came with the development of vaccines against hepatitis B, and later in a still-unrealised search for a hepatitis C vaccine.
- Some scientists lobbied for retirement facilities for the chimpanzees, but many began seriously to consider euthanasia as the only practical way to alleviate the crisis. Ironically, it was the AIDS epidemic in the mid-1980s which 'saved' the very chimpanzees that were 'used up'. Once again, they became 'surrogate human beings', this time in the development of HIV vaccines.
- Yet by the mid-1990s, scientists began to turn to human volunteers for the initial testing of HIV vaccines, leaving large numbers of 'redundant' chimpanzees, which have a lifespan of up to 40 years. A report by the US National Research Council (1997) concluded that chimpanzees should be afforded special consideration, on ethical grounds, over other non-humans, and that euthanasia isn't an acceptable means of population control.
- This is consistent with one of the findings of a MORI poll conducted in the UK, namely that people are more likely to oppose experiments on monkeys than those on mice. Only those experiments designed to test or develop drugs to treat childhood leukaemia were seen as justifying monkeys' suffering (Aldhous *et al.*, 1999). Research using great apes (gorillas, chimpanzees, bonobos, and orang-utans) was banned in 1998 (Brown, 2004).
- Wise (2000) argues that animals should have full rights under the law. Goodall describes Wise's book as the 'animals' Magna Carta' (Mee, 2000).

(Based on Mahoney, 1998)

Speciesism: extending the medical justification argument

According to Gray (1991), most people (both experimenters and animal rights activists) would accept the ethical principle that inflicting pain is wrong. But we're sometimes faced with having to choose between different ethical principles, which may mean having to choose between human and non-human suffering. Gray believes that *speciesism* (discriminating against and exploiting animals because they belong to a particular [non-human] species: Ryder, 1990) is justified, and argues that:

Not only is it not wrong to give preference to the interests of one's own species, one has a duty to do so.

Such a moral choice involves establishing a *calculus* (Dawkins, 1990), which pits the suffering of non-humans against the human suffering which the former's use will alleviate. For Gray (1991):

In many cases the decision not to carry out certain experiments with animals (even if they would inflict pain or suffering) is likely to have the consequence that more people will undergo pain or suffering that might otherwise be avoided.

One of the problems associated with the pro-speciesism argument is that medical advance may become possible only after extensive development of knowledge and scientific understanding in a particular field (Gray, 1991). In the meantime, scientific understanding may be the only specific objective that the experiment can readily attain. It's at this interim stage that the suffering imposed on experimental animals will far outweigh any (lesser) suffering eventually avoided by people, and this is at the core of the decisions that must be made by scientists and ethical committees.

PSYCHOLOGISTS AS PRACTITIONERS

Clinical psychologists (as well as educational psychologists, psychotherapists, psychiatrists, social workers, nurses, counsellors, and other professionals) are concerned with bringing about *psychological change.* It's in their capacity as agents of change that clinical psychologists face their greatest ethical challenges (see Chapter 1).

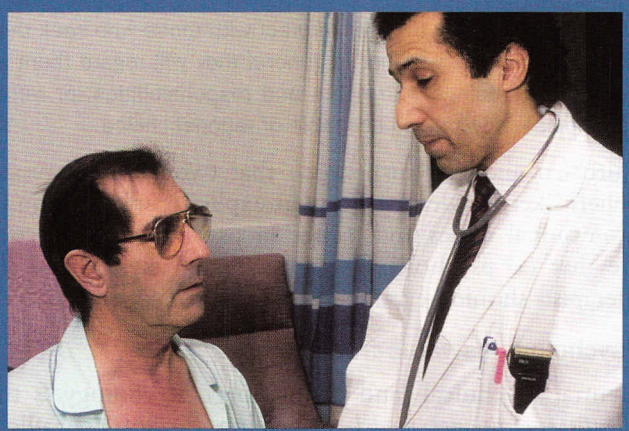
ASK YOURSELF...

- Consider some of the ethical issues faced by psychologists attempting to change other people's behaviour.
- Some are of a general nature, such as freedom versus determinism (see Chapter 49), others will overlap with ethical principles governing research (such as confidentiality and informed consent), and yet others may be specific to particular therapeutic approaches (see Chapter 45).

According to Fairbairn & Fairbairn (1987), clinical psychologists:

... must decide how they will interact with those who seek their help; for example, whether in general they will regard them as autonomous beings with rights and responsibilities, or rather as helpless individuals, incapable of rational choice.

Fairbairn and Fairbairn argue that two quite common beliefs likely to detract from an explicit consideration of professional ethics and values in psychological practice are that (a) psychology is a value-free science, and (b) therapists should be value-neutral or 'non-directive'.



Psychology as value-free science

Central to clinical (and counselling) psychology is the *scientist–practitioner model* of helping (Dallos & Cullen, 1990). This sees clinical psychology as being guided by, and operating within, the framework of the general scientific method (see Chapters 3 and 45). If clinical psychologists view clinical psychology as having firm foundations in positivist science, they may disregard ethics because these aren't amenable to objective consideration. But even if the psychological knowledge used in clinical practice was always the result of the application of an objective scientific method, *moral* questions of an interpersonal kind are bound to arise at the point at which it's *applied* (Fairbairn & Fairbairn, 1987).

This distinction between possession of knowledge and its application ('science' versus 'technology') is fundamental to any discussion of ethics, because it's related to the notion of *responsibility.* Presumably, clinical psychologists *choose* which techniques to use with clients and how to use them. The mere existence (and even the demonstrated effectiveness) of certain techniques doesn't in itself mean that they *must* be used. Similarly, the kind of research which clinical psychologists consider worth doing (and which then provides the scientific basis for the use of particular techniques) is a matter of choice, and reflects views regarding the nature of people and how they can be changed (see Chapters 1 and 2).

Box 48.7 Criticisms of scientific behaviour therapy and modification

- Based on the scientist-practitioner model, behaviour therapy and modification tend to devalue and thereby dehumanise their clients by treating people, for 'scientific' purposes, as if they were 'organisms' as opposed to 'agents', helpless victims of forces outside their control.
- This criticism also applies to medical psychiatry and classical psychoanalysis, except that both see the controlling forces as being internal (organic abnormalities or intrapsychic forces, respectively) as opposed to environmental contingencies (see Chapters 2 and 45).

This passive patient looks vacantly at the doctor – the expert and authority figure

- Clients soon come to believe that they're abnormal, helpless, and also worthless, because this is part of the culture-wide stereotype of 'mental illness' (see Chapter 43). Negative self-evaluation and passivity characterise many, if not most, mental health clients, who think and behave like passive organisms. The solution lies in helping people recover, or discover, their agency.

(Based on Trower, 1987)

Therapists as value-neutral and non-directive

This second major issue is about the therapist or psychologist functioning as something less than a complete person within the therapeutic situation. Providing help and support in a non-directive, value-free way is a tradition for psychotherapists and counsellors (Fairbairn & Fairbairn, 1987). However, such an approach may seem to require remaining aloof and distant from the client which, in turn, may entail not treating the client with respect as a person, since this requires the therapist to recognise that the client is a person like him- or herself.

ASK YOURSELF...

- Is there a difference between, say, client-centred therapy and psychoanalysis in terms of this possible aloofness and failure to treat the client 'respectfully'? (See Chapter 45.)

Carl Rogers (right) in a group therapy session

ASK YOURSELF...

- Do you believe that it's possible for therapists not to have any influence over their clients/patients?

The influence of the therapist

Adopting what's thought to be a value-free position in therapy may lead therapists to deny the importance or influence of their own moral values, which are often hidden in therapy. This kind of influence is much more subtle and covert than the coercion that can operate on hospitalised psychiatric patients, even voluntary ones. The in-patient is subjected to strong persuasion to accept the treatment recommendations of professional staff. As Davison & Neale (1994) observe:

> Even a 'voluntary' and informed decision to take psychotropic medication or to participate in any other therapy regimen is often (maybe usually) less than free.

CRITICAL DISCUSSION 48.6 Therapist influence in psychodynamic and behaviour therapy

- The issue of the therapist's influence on the patient/client has been central to a long-standing debate between traditional (psychodynamic) psychotherapists and behaviour therapists (who are usually clinical psychologists by training: see Chapter 45).
- Psychotherapists regard behaviour therapy as unacceptable (even if it works), because it's manipulative and demeaning of human dignity. By contrast, they see their

own methods as fostering the autonomous development of the patient's inherent potential, helping the patient to express his/her true self, and so on. Instead of influencers, they see themselves as 'psychological midwives', present during the 'birth', possessing useful skills, but there primarily to make sure that a natural process goes smoothly.

- However, this is an exaggeration and misrepresentation of both approaches. For many patients, the 'birth' probably wouldn't happen at all without the therapist's intervention, and s/he undoubtedly influences the patient's behaviour. Conversely, behaviour therapists are at least partly successful because they establish active, cooperative relationships with their patients, who play much more active roles in the therapy than psychotherapists believe.
- All therapists, of whatever persuasion, if they're at all effective, influence their patients. Both approaches comprise a situation in which one human being (the therapist) tries to act in a way that enables another human being to act and feel differently, and this is as true of psychoanalysis as it is of behaviour therapy.

(Based on Wachtel, 1977)

The crucial issue is the *nature* of the therapist's influence, rather than whether or not influence occurs. One ethical issue is whether the influence is exerted in a direction that is in the patient's interest, or in the service of the therapist's needs. Another is whether the patient is fully informed about the kind of influence the therapist wishes to exert, and the kind of ends being sought (the issue of *informed consent*). Therapist *neutrality* is a myth: therapists influence their clients in subtle yet powerful ways. According to Davison and Neale (1994):

> Unlike a technician, a psychiatrist cannot avoid communicating and at times imposing his own values upon his patients. The patient usually has considerable difficulty in finding the way in which he would wish to change his behaviour, but as he talks to the psychiatrist his wants and needs become clearer. In the very process of defining his needs in the presence of a figure who is viewed as wise and authoritarian, the patient is profoundly influenced. He ends up wanting some of the things the psychiatrist thinks he should want.

In the above quotation, we can add 'psychologist' and 'psychotherapist' to 'psychiatrist'.

Freedom and behavioural control

While a behavioural technique such as *systematic desensitisation* (SD) is limited mainly to anxiety reduction, this can at least be seen as enhancing the patient's freedom, since anxiety is one of the greatest restrictions on freedom. By contrast, methods based on *operant conditioning* can be applied to almost any aspect of a person's behaviour. Those who use operant methods (such as the *token economy*/TE) often describe their work rather exclusively in terms of *behavioural control,* subscribing to Skinner's (1971) view of freedom as an illusion (see Chapter 49).

Wachtel (1977) believes that when used in institutional settings (such as with long-term schizophrenic patients in psychiatric hospitals), the TE is so subject to abuse that its use is highly questionable. It may be justifiable if it works, and if there's clearly no alternative way of rescuing a patient from an empty and destructive existence. But as a routine part of how society deals with deviant behaviour, this approach raises very serious ethical questions. One of these relates to the question of *power.* Like the experimental 'subject' relative to the experimenter, the patient is powerless relative to the institutional staff responsible for operating the token economy programme:

> Reinforcement is viewed by many – proponents and opponents alike – as somehow having an inexorable controlling effect upon the person's behaviour and rendering him incapable of choice, reducing him to an automaton or duly wound mechanism ... (Wachtel, 1977)

The alarming feature of the TE is the reinforcing agent's power to deprive un-cooperative patients physically of 'privileges' (see Box 45.7, page 825).

The abuse of patients by therapists

In recent years, there's been considerable criticism of psychotherapy (especially Freudian psychoanalysis), including its ethical shortcomings. Masson (1988) believes that there's an imbalance of power involved in the therapeutic relationship, and individuals who seek therapy need protection from the therapist's constant temptation to abuse, misuse, profit from and bully the client. The therapist has almost absolute emotional power over the patient, and Masson catalogues many examples of patients' emotional, sexual, and financial abuse at their therapists' hands.

Not surprisingly, Masson's attack has stirred up an enormous controversy. Holmes (1992) agrees with the core of Masson's (1992) argument, namely that:

> No therapist, however experienced or distinguished, is above the laws of the unconscious, and all should have access to supervision and work within a framework of proper professional practice.

However, in psychotherapy's defence, Holmes points out that exploitation and abuse are by no means confined to psychotherapy. Lawyers, university teachers, priests, and doctors are also sometimes guilty (the case of Harold Shipman, the serial-killer doctor, being one, albeit rather extreme, example). All these professional groups have ethical standards and codes of practice (often far more stringent than the law of the land), with disciplinary bodies which impose severe punishments (usually expulsion from the profession). We shouldn't condemn an entire profession because of the transgressions of a small minority.

CONCLUSIONS

This chapter has considered the ethics of psychological research, with both human participants and animal subjects, as well as ethical issues arising from the psychologist's role as a professional involved in behaviour change. Discussion of ethical issues has, in various ways, struck at the heart of psychology itself, requiring us to ask what psychology is for. According to Hawks (1981), prevention rather than cure should be a primary aim of psychology, enabling people to cope by themselves, without professional help, thus 'giving psychology away' to people/clients. For Bakan (1967), the significant place in society of the psychologist is more that of the teacher than expert or technician.

CHAPTER SUMMARY

- Psychology's focus of study consists of **sentient** things. This makes every psychological investigation an **ethical situation**, with research determined as much by its effects on those being studied as by what psychologists want to find out.
- The BPS's *Ethical Principles* identifies several issues relating to research with human participants, including **consent/informed consent**, **deception**, **protection of participants**, **debriefing** and **confidentiality**.
- Even if a participant has been fully informed about an experimental procedure, this doesn't guarantee **informed consent**.
- **Debriefing** must take place at the earliest opportunity following the use of **deception**, and an experimenter must ensure that participants leave the experimental situation in at least as positive a frame of mind as when they entered.
- The BPS and APA codes and guidelines are periodically revised in the light of changing social and political contexts. This indicates that there are **no absolute** or **universal ethical truths**.
- Ethical criticisms of Milgram's obedience experiments helped trigger the debate regarding the ethics of research within psychology as a whole.
- The distress that Milgram's participants experienced wasn't an intended or deliberate effect of the experimental procedure. Participants were thoroughly '**dehoaxed**' at the end of the experiment, and Milgram also argued that participants were **free** to obey or disobey.
- While deception is unethical if it prevents participants from giving informed consent, those who've been deceived generally approve of it retrospectively. Deception may sometimes be the best/only way of obtaining valuable insights into human behaviour.
- **Socially sensitive research** (SSR) refers to studies with potential consequences or implications, either for the individual participants or for the groups they represent.
- While ethical codes serve to protect individual participants, underlying assumptions may harm the **social groups** they represent. Formal codes neglect wider issues regarding the ethical acceptability of SSR.
- Psychological research must be **socially meaningful** (the **ethical imperative**). This applies particularly to the work of social psychologists.
- Three possible solutions to the **double obligation dilemma** (DOD) are conducting a **cost–benefit analysis** (C-BA), and obtaining either **presumptive consent** or **prior general consent**.
- While the physical suffering of experimental animals is obvious, mental suffering is less overt. There are several **safeguards** to protect animal subjects, including the BPS *Guidelines for the Use of Animals in Research,* the Animals Act (and the Home Office Inspectors who monitor its implementation), and research into animal suffering.
- Despite these safeguards, the very existence of the Animals Act condones the use of animals. Only 'unnecessary' pain and distress are illegal, and the Medicines Act requires that all new medicines undergo a range of tests on animals before they can be tested on humans.
- The main justifications for animal experimentation are the **pursuit of scientific knowledge** and the **advancement of medicine**. The medical justification argument presupposes that medical benefits have actually resulted from animal experiments. However, scientific opinion is divided about this.
- According to **speciesism**, we're morally obliged to inflict pain on animals in order to reduce potential human suffering. The speciesism argument assumes a greater significance when the non-humans in question are chimpanzees and other **primates**.
- Clinical psychologists and other **agents of change** are likely to neglect professional ethics, because of the twin beliefs that psychology is a **value-free** science (as embodied in the **scientist–practitioner model** of helping) and that therapists should be **value-neutral**/'**non-directive**'.
- However effective a particular technique may be, clinical psychologists still *choose* which techniques to use and what research is worth doing. **Behaviour therapy** and **modification** treat people as helpless organisms, resulting in low self-esteem and passivity.
- **Psychiatric in-patients** are subjected to **subtle coercion** to accept particular treatments, and therapists may exert an even more covert influence over their clients.
- **All** therapists, psychodynamic and behavioural alike, **influence** their clients/patients. The crucial issue is the **nature** of that influence.
- The **token economy** (TE) is often described in terms of **behavioural control**, and within institutions, staff have the **power** to deprive patients of 'privileges'.

There's also a power **imbalance** between therapists and their clients. In both situations, abuse of power may occur.

Links with other topics/chapters

- The change from 'subject' to 'participant' in the earlier and later BPS *Ethical Principles* can partly be attributed to the influence of feminist psychologists, who've also helped to bring about the removal of sexist language from BPS and APA journals as a matter of policy (Chapter 47).
- Part of Milgram's justification of his obedience experiments is his belief in his participants' *free will* (Chapter 49).
- Talking about the aim of 'human betterment' in relation to the 'double obligation dilemma' raises important questions about basic values. It opens out the ethical debate in such a way that values must be addressed and recognised as part of the research process (something advocated very strongly by feminist psychologists (Chapter 47).
- Crucial methodological issues raised by the double obligation dilemma include *experimental realism* and *external validity* or *mundane realism* (Chapters 3, 26 and 27).
- Traditionally, the most deeply informative experiments in social psychology include those examining how participants resolve conflicts, such as Asch's studies of *conformity* (truth versus conformity: Chapter 26), Latané and Darley's *bystander intervention* studies (getting involved in another's troubles versus not getting involved: Chapter 30), and Milgram's own *obedience experiments* (internal conscience versus external authority: Chapter 27).

FREE WILL AND DETERMINISM, AND REDUCTIONISM

INTRODUCTION AND OVERVIEW

Any discussion of psychology's scientific status raises fundamental questions about the nature of the person (see Chapter 3) or, at least, the image of the person that underlies major psychological theories (see Chapter 2), and that is implicit in much of the study of human behaviour. This chapter discusses two of these fundamental questions.

One question, debated by western philosophers for centuries, is whether we choose to act as we do, or whether behaviours are caused by influences beyond our control (*free will versus determinism*). The other, which has a shorter history and is debated by philosophers of science, concerns the validity of attempts to explain complex wholes in terms of their constituent parts (*reductionism*). One example of this is the relationship between the mind (or consciousness) and the brain (the '*mind–body problem*').

FREE WILL AND DETERMINISM

What is free will?

One way of approaching this question is to consider examples of behaviour where 'free will' (however defined) is clearly absent.

CASE STUDY 49.1: Tourette's disorder

Tim is 14 and displays a variety of twitches and tics. His head sometimes jerks and he often blinks and grimaces. Occasionally, he blurts out words, usually vulgarities. He doesn't mean to do it and is embarrassed by it, but he cannot control it. Because of his strange behaviour, most other children avoid him. His isolation and embarrassment are interfering with his social development. Tim suffers from a rare condition called *Tourette's disorder.*

(From Holmes, 1994)

ASK YOURSELF...

- What specific aspects of Tim's disorder are relevant to understanding the concept of 'free will'?
- If you think Tim lacks free will, what led you to this conclusion?
- Think of other behaviours (normal or abnormal) that demonstrate a lack of free will.

Intuition tells us that people have the ability to choose their own courses of action, determine their behaviour and, to this extent, they have *free will.* However, this freedom is exercised only within certain physical, political, sociological, and other environmental constraints. Yet the positivistic, mechanistic nature of scientific psychology (see Chapter 3) implies that behaviour is *determined* by external (or internal) events or stimuli, and that people are passive responders. To this extent, people *aren't free. Determinism* also implies that behaviour occurs in a regular, orderly manner which (in principle) is totally predictable. For Taylor (1963), determinism maintains that:

> In the case of everything that exists, there are antecedent conditions, known or unknown, given which that thing could not be other than it is ... More loosely, it says that everything, including every cause, is the effect of some cause or causes; or that everything is not only determinate but causally determined.

'Everything that exists' includes people and their thoughts and behaviours, so a 'strict determinist' believes that thought and behaviours are no different from (other) 'things' or events in the world. However, this begs the question as to whether thoughts and behaviours are the same *kind of thing* or *event* as, say, chemical reactions in a test tube, or neurons firing in the brain. We don't usually ask if the chemicals 'agreed' to combine in a certain way, or if the neurons 'decided' to fire. Unless we were trying to be witty, we'd be guilty of *anthropomorphism* (attributing human abilities and characteristics to non-humans or things).

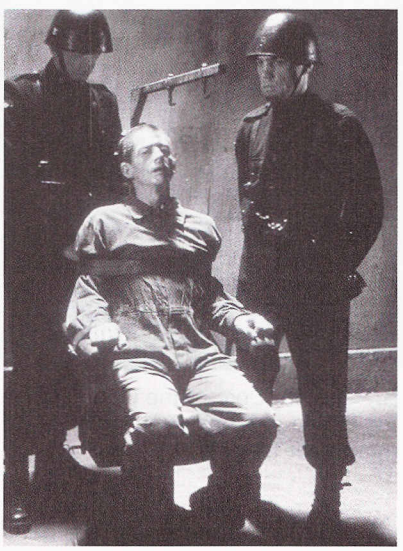
This painting by Gustave Doré of the Old Testament story of Lot's wife being turned to stone (*The Rescue of Lot*) illustrates the human capacity for free will

It's only *people* who can agree and make decisions. These abilities and capacities form part of our concept of a person, which, in turn, forms an essential part of 'everyday' or common-sense psychology (see Chapter 1). Agreeing and deciding are precisely the kinds of things we do *with our minds* (they're mental processes or events), and to be able to agree and make decisions, it's necessary to 'have a mind'. So free will implies having a mind. However, having a mind doesn't imply free will: it's possible that decisions and so on are themselves caused (determined), even though they seem to be freely chosen.

ASK YOURSELF...

- Try to explain what someone means when s/he says 'I had no choice but to ...' or 'You leave me no choice ...'.
- Can you interpret this in a way that's consistent with a belief in free will?

Different meanings of 'free will'



One of the difficulties with the free will versus determinism debate is the ambiguity of the concepts involved.

Having a choice

If we have choice, then we *could* behave differently given the same circumstances. This contrasts sharply with a common definition of determinism, namely that things could only have happened as they did, given everything that happened previously (see above).

Not being coerced or constrained

If someone puts a loaded gun to your head and tells you to do something, your behaviour is clearly not free: you've been forced to act this way. This is usually where the philosophical debate about 'free will' begins, and is related to what James (1890) called *soft determinism* (see pages 890–891).

John Hurt as Winston Smith in the film of George Orwell's *1984*

Voluntary behaviour

If 'involuntary' conveys reflex behaviour (such as the eye-blink response to a puff of air directed at the eye), then 'voluntary' implies 'free' (the behaviour isn't automatic). By definition, most behaviour (human and non-human) *isn't* reflex, nor is it usually the result of coercion. So is most behaviour free?

Box 49.1 Evidence for the distinction between voluntary and involuntary behaviour

- Penfield's (1947) classic experiments involved stimulating the cortex of patients about to undergo brain surgery (see Chapter 4, page 60).
- Even though the cortical area being stimulated was the same as that which is involved when we normally ('voluntarily') move our limbs, patients reported feeling that their arms and legs were being moved passively, quite a different experience from initiating the movement themselves.
- This demonstrates that the subjective experience (*phenomenology*) of the voluntary movement of one's limbs cannot be reduced to the stimulation of the appropriate brain region (otherwise Penfield's patients shouldn't have reported a difference). Doing things voluntarily simply *feels* different from the same things 'just happening'.
- Similarly, Delgado (1969) stimulated a part of the primary motor area in a patient's left hemisphere, causing the patient to form a clenched fist with his right hand. When asked to try to keep his fingers still during the next stimulation, the patient couldn't do it and commented, 'I guess, Doctor, that your electricity is stronger than my will'.
- These examples support the claim that having free will is an undeniable part of our subjective experience of ourselves as people. The sense of self is most acute (and important and real for us) where moral decisions and feelings of responsibility for past actions are involved (Koestler, 1967). See text and Box 49.2 for further discussion of free will and moral responsibility.

One demonstration of people's belief in their free will is *psychological reactance* (Brehm, 1966; Brehm & Brehm, 1981: see Chapter 9). A common response to the feeling that our freedom is being threatened is the attempt to regain or reassert it, which is related to the need to be free from others' controls and restrictions, to determine our own actions and not be dictated to. A good deal of contrary (resistant) behaviour, otherwise known as 'bloody-mindedness' ('Don't tell me what to do!') seems to reflect this process (Carver & Scheier, 1992).

Similar to this need to feel free from others' control is *intrinsic motivation* or *self-determination* (Deci, 1980; Deci & Ryan, 1987). This refers to people's intrinsic interest in things, such that they don't need to be offered extrinsic incentives for doing them. Engaging in such activities is motivated by the desire for competence and self-determination.

So what happens if someone is offered an extrinsic reward for doing something which is already interesting and enjoyable in itself? Lepper *et al.* (1973) found that the activity loses its intrinsic appeal, and motivation is

reduced (the *paradox of reward*). This has implications for accounts of moral development based on learning theory principles, especially operant conditioning (see Chapters 11 and 35).

ASK YOURSELF...

- How could you account for the 'paradox of reward' in terms of attributional principles, specifically, internal and external causes? (See Chapter 23.)

Deliberate control

Norman & Shallice (1986) define divided attention as an upper limit to the amount of processing that can be performed on incoming information at any one time. They propose three levels of functioning, namely *fully automatic processing, partially automatic processing,* and *deliberate control* (see Chapter 13). Deliberate control corresponds to free will.

Driving a car is a sensory–motor skill, performed by experienced drivers more or less automatically. It doesn't require deliberate, conscious control, unless some unexpected event disrupts the performance (such as putting your foot on the brake when there's an obstacle ahead: this is a 'rule of the game'). However, on an icy road this can be risky, since the steering wheel has a different 'feel' and the whole driving strategy must be changed. After doing it several times, this too may become a semi-automatic routine:

> But let a little dog amble across the icy road in front of the driver, and he will have to make a 'top-level decision' whether to slam down the brake, risking the safety of his passengers, or run over the dog. And if, instead of a dog, the jaywalker is a child, he will probably resort to the brake, whatever the outcome. It is at this level, when the pros and cons are equally balanced, that the subjective experience of freedom and moral responsibility arises ... (Koestler, 1967)

As we move downwards from conscious control, the subjective experience of freedom diminishes. According to Koestler:

> Habit is the enemy of freedom ... Machines cannot become like men, but men can become like machines.

Koestler also maintains that the second enemy of freedom is very powerful (especially negative) emotion:

> When [emotions] are aroused, the control of decisions is taken over by those primitive levels of the hierarchy which the Victorians called 'the Beast in us' and which are in fact correlated to phylogenetically older structures in the nervous system.

The arousal of these structures results in 'diminished responsibility' and 'I couldn't help it' (Koestler, 1967).

ASK YOURSELF...

- In Koestler's quote above, (a) what does 'phylogenetically older structures' mean? and (b) what are the major 'primitive levels of the hierarchy' correlated with these structures? (See Chapter 4, page 67.)

Robert Louis Stephenson's *The Strange Case of Dr Jekyll and Mr Hyde* illustrates how the arousal of powerful, primitive emotions can lead to claims of 'diminished responsibility'

Why are psychologists interested in the concept of free will?

As noted in the *Introduction and overview,* the philosophical debate about free will and determinism is centuries old. It can be traced back at least to the French philosopher Descartes (1596–1650), whose ideas had a great influence on both science in general and psychology in particular. For much of its history as a separate, scientific discipline, psychology has operated as if there were no difference between natural, physical phenomena and human thought and behaviour (see Chapter 3).

During the period 1913–1956, psychology (at least in the USA) was dominated by behaviourism, Skinner being particularly influential. Skinner's beliefs about the influence of mental phenomena on behaviour, and those concerning free will, are discussed below (see pages 892–893).

ASK YOURSELF...

- Try to identify some (other) ways in which the issue of free will is relevant to psychological theory and practice. For example, how does the notion of free will relate to criteria for defining and diagnosing mental disorders? (See Chapter 43.)

Free will and psychological abnormality

Definitions of abnormality, and the diagnosis and treatment of mental disorders, often involve implicit or explicit judgements about free will and determinism. In a general sense, mental disorders can be seen as the partial

or complete breakdown of the control people normally have over their thoughts, emotions, and behaviours. For example, *compulsive* behaviour is, by definition, behaviour which a person cannot help but do: s/he is 'compelled' to do it. People are *attacked* by panic, *obsessed* by thoughts of germs, or become the *victims* of thoughts which are inserted into their mind from outside and are under external influence (see Chapter 44). In all these examples, things are happening to, or being done to, the individual (instead of the individual doing them), both from their own perspective and that of a psychologist or psychiatrist.

Being judged to have lost control (possession of which is usually thought of as a major feature of normality), either temporarily or permanently, is a legally acceptable defence in cases of criminal offences.

Box 49.2 Forensic psychiatry, diminished responsibility and the law

- *Forensic psychiatry* deals with assessment and treatment of mentally disturbed offenders (see Chapter 46). The Mental Health Act 1983 has several clauses providing for the compulsory detention of prisoners (either while awaiting trial or as part of their sentences) in hospital. Psychiatrists, as expert witnesses, can play important roles in advising the Court about:

  (a) fitness to plead
  (b) mental state at the time of the offence
  (c) diminished responsibility.

- The defence of *diminished responsibility* (for murder) was introduced in England and Wales in the 1957 Homicide Act, largely replacing the plea of 'not guilty by reason of insanity', which was based on the 'McNaughton Rules' of 1843.

  If accepted, there's no trial and a sentence of manslaughter is passed. If not accepted, a trial is held and the jury must decide whether the accused (at the time the crime was committed) was suffering from an abnormality of mind, and if so, whether it was such as to impair substantially his/her responsibility.

- Peter Sutcliffe, the 'Yorkshire Ripper', was found guilty of the murder of 13 women and the attempted murder of seven others, despite his defence that he heard God's voice telling him to 'get rid' of prostitutes. In finding him guilty of murder, the jury didn't necessarily reject the defence's argument that he was suffering from paranoid schizophrenia, only that it didn't constitute a mental abnormality of sufficient degree to impair substantially responsibility for his acts. Sutcliffe was sentenced to 20 concurrent terms of life imprisonment, which he served initially in an ordinary prison before being sent to Broadmoor Special Hospital.

(Based on Gelder *et al.*, 1989; Prins, 1995)

Peter Sutcliffe, the 'Yorkshire Ripper'

Free will and moral accountability

Underlying the whole question of legal (and moral) responsibility is the presupposition that people are, at least some of the time, able to control their behaviours and choose between different courses of action. How else could we ever be held responsible for any of our actions? In most everyday situations and interactions, we attribute responsibility, both to ourselves and others, unless we have reason to doubt it. According to Flanagan (1984):

> It seems silly to have any expectations about how people ought to act, if everything we do is the result of some inexorable causal chain which began millennia ago. 'Ought', after all, seems to imply 'can', therefore, by employing a moral vocabulary filled with words like 'ought' and 'should', we assume that humans are capable of rising above the causal pressures presented by the material world, and, in assuming this we appear to be operating with some conception of freedom, some notion of free will.

Free will as an issue in major psychological theories

Most major theorists in psychology have addressed the issue of free will and determinism, including James, Freud, Skinner and Rogers.

James and soft determinism

As we saw in Chapter 1, James pioneered psychology as a separate, scientific discipline. In *The Principles of Psychology* (1890), he devoted a whole chapter to the 'will', which he related to attention:

> The most essential achievement of the will ... when it is most 'voluntary' is to attend to a different object and hold it fast before the mind ... Effort of attention is thus the essential phenomenon of will.

For James, there was a conflict. Belief in determinism seemed to fit best with the scientific view of the world, while belief in free will seemed to be required by our social, moral, political, and legal practices, as well as by our personal, subjective experience (see above). His solution to this conflict was two-fold.

1. He distinguished between the scientific and non-scientific worlds. Psychology as a science could progress only by assuming determinism, but this doesn't mean that belief in free will must be abandoned in other contexts. So, scientific explanation isn't the only useful kind of explanation.
2. He drew a further distinction between *soft* and *hard* determinism. According to *soft determinism,* the question of free will depends on the type(s) of cause(s) our behaviour has, *not* whether it's caused or not caused (the opposite of 'not caused' is 'random', not 'free'). If our actions have, as their immediate (proximate) cause, processing by a system such as *conscious mental life* (CML, which includes consciousness, purposefulness, personality and personal continuity), then they count as free, rational, voluntary, purposive actions. According to *hard determinism,* CML is itself caused, so that the immediate causes are only part of the total causal chain which results in the behaviour we're trying to explain. Therefore, as long as our behaviour is caused at all, there's no sense in which we can be described as acting freely.

Freud and psychic determinism

Although in most respects Freud's and Skinner's ideas about human behaviour are diametrically opposed, they shared the fundamental belief that free will is an *illusion.* However, in keeping with their theories as a whole, their reasons are radically different.

ASK YOURSELF...

- Based on what you already know about Freud's psychoanalytic theory, try to identify those parts that are most relevant to his rejection of free will.

According to Strachey (1962):

> Behind all of Freud's work ... we should posit his belief in the universal validity of the law of determinism ... Freud extended the belief (derived from physical phenomena) uncompromisingly to the field of mental phenomena.

Similarly, Sulloway (1979) maintains that all of Freud's work in science (and Freud saw himself very much as a scientist) was characterised by an abiding faith in the notion that all vital phenomena, including psychical (psychological) ones, are rigidly and lawfully determined by the principle of cause and effect. One major example of this was the extreme importance he attached to the technique of *free association.*

Box 49.3 How 'free' is Freud's 'free association'?

- 'Free association' is a misleading translation of the German *'freier Einfall'*, which conveys much more accurately the intended impression of an uncontrollable 'intrusion' (*Einfall*) by preconscious ideas into conscious thinking. In turn, this preconscious material reflects unconscious ideas, wishes, and memories (what Freud was really interested in), since here lie the principal causes of neurotic problems.
- It's a great irony that 'free' association should refer to a technique used in psychoanalysis meant to reveal the *unconscious* causes of behaviour. It's because the causes of our thoughts, actions, and supposed choices are unconscious (mostly *actively repressed*), that we *think* we're free.
- Freud's application of this general philosophical belief in causation to mental phenomena is called *psychic determinism* (see Chapter 42, page 749).

(Based on Sulloway, 1979)

For Freud, part of what 'psychic determinism' conveyed was that in the universe of the mind, there are no 'accidents'. No matter how apparently random or irrational behaviour may be (such as '*parapraxes*' or 'Freudian slips'), unconscious causes can always account for them, and this also applies to hysterical symptoms and dreams. As Gay (1988) states, 'Freud's theory of the mind is ... strictly and frankly deterministic'. However, the following points should be borne in mind:

- Freud accepted that true accidents, in the sense of forces beyond the victim's control (e.g. being struck by lightning), can and do occur, and aren't unconsciously caused by the victim
- one of the aims of psychoanalysis is to 'give the patient's ego *freedom* to decide one way or another' (Freud, quoted in Gay, 1988), so therapy rests on the belief that people *can* change. However, Freud saw the extent of possible change as being very limited (see Critical Discussion 45.2, page 818)
- one aspect of psychic determinism is *overdetermination;* that is, much of our behaviour has multiple causes, both conscious and unconscious. So although our conscious choices, decisions, and intentions may genuinely influence behaviour, they never tell the whole story
- despite never having predicted in advance what choice or decision a patient would make, Freud maintained that these aren't arbitrary, and can be understood as revealing personality characteristics (Rycroft, 1966). What Freud often did was to explain his patients' choices, neurotic symptoms, and so on not in terms of causes (the *scientific* argument), but by trying to make sense of them and give them meaning

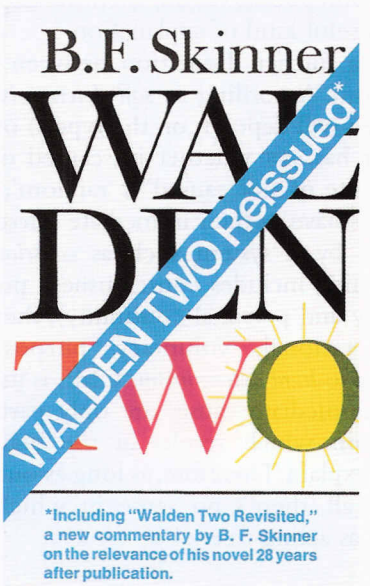
(the *semantic* argument). Indeed, the latter is supported by the title of, arguably, his greatest book, *The Interpretation of Dreams* (1900) (as opposed to *The 'Cause' of Dreams*).

Skinner and the illusion of free will

As we noted above, Skinner, like Freud, sees free will as an illusion. However, while Freud focused on 'the mind', especially unconscious thoughts, wishes, and memories, Skinner's *radical behaviourism* eliminates all reference to mental or private states as part of the explanation of behaviour (including theories like Freud's!).

Although Skinner doesn't deny that pain and other internal states exist, they have no 'causal teeth' and hence no part to play in scientific explanations of (human) behaviour (Garrett, 1996). Free will (and other 'explanatory fictions') cannot be defined or measured objectively, nor are they needed for successful prediction and control of behaviour (for Skinner, the primary aims of a *science of behaviour*). It's only because the causes of human behaviour are often hidden from us in the environment, that the myth or illusion of free will survives.

ASK YOURSELF...



- Given what you know about Skinner's theory of operant conditioning and his 'analysis of behaviour', try to identify the causes of human behaviour that he believes are often hidden from us in the environment. (See Chapters 2 and 11.)

Skinner argues that when what we do is dictated by force or punishment, or by their threat (negative reinforcement), it's obvious to everyone that we're not acting freely. For example, when the possibility of prison stops us committing crimes, there's clearly no choice involved, because we know what the environmental causes of our behaviour are. Similarly, it may sometimes be very obvious which positive reinforcers are shaping behaviour (a bonus for working overtime, for example).

However, most of the time we're unaware of environmental causes, and it looks (and feels) as if we're behaving freely. Yet all this means is that we're free of punishments or negative reinforcement, and behaviour is still determined by the pursuit of things that have been positively reinforced in the past. When we perceive others as behaving freely, we're simply unaware of their reinforcement histories (Fancher, 1996).

Box 49.4 The freedom myth and the rejection of punishment

- In *Beyond Freedom and Dignity,* Skinner (1971) argued that the notion of 'autonomous man', upon which so many of western society's assumptions are based, is false and has many harmful consequences.
- In particular, the assumption that people are free requires that they're constantly exposed to punishment and its threat as a negative reinforcer (Fancher, 1996).
- In his 1948 novel *Walden Two,* Skinner (1948b) describes a utopian society where only mutual reinforcement is used – never punishment or negative reinforcement.

ASK YOURSELF...

- What *ethical* issues are raised by Skinner's advocacy of a utopian society like *Walden Two?*
- In what ways does this Utopia reflect Skinner's beliefs about the aims of a scientific psychology?

Skinner's views on bettering society (through strict behavioural control or engineering) caused an enormous backlash from critical audiences and the general public. This is reflected in his appearance on the cover of *Time* magazine in September 1971. Rogers claimed that Skinner's utopian vision was indistinguishable from Orwell's *Nineteen Eighty-Four,* a nightmarish *dystopia,* which warns against a punitive society where people are treated as automatons by those in power (O'Donohue & Ferguson, 2001).

Clearly, Skinner's belief that free will is an illusion conflicts with the need to attribute people with free will if we're to hold them (and ourselves) morally (and legally) responsible for their behaviour. Skinner (1971) himself acknowledges that freedom and dignity are:

> ... essential to practices in which a person is held responsible for his conduct and given credit for his achievements.

Afghan men in Kabul at a cockfighting match, very popular with gamblers in this war-torn country. Where activities like these are such a part of the culture, are individuals responsible for their behaviour?

However, Skinner equates 'good' and 'bad' with 'beneficial to others' (what's rewarded) and 'harmful to others' (what's punished) respectively, thus removing morality from human behaviour. For Skinner, 'oughts' aren't 'moral imperatives': they reflect *practical,* rather than moral, guidelines and rules. (Morea, 1990).

According to Garrett (1996), if we're rational, thinking creatures, capable of assessing ethical rules and principles, and evaluating the goodness of our lives, then we have all the freedom needed reasonably to prefer democratic to non- (or anti-) democratic forms of government (as expressed in *Walden Two* and *Beyond Freedom and Dignity*).

A further consequence of Skinner's rejection of the notion of 'autonomous man' is what Ringen (1996) calls the *behaviour therapist's dilemma.*

Box 49.5 The behaviour therapist's dilemma

- There's a deep tension between two features of modern clinical psychology.
- On the one hand, Skinner (1971) argues that scientific considerations support *radical behaviourism* as the most appropriate framework for understanding and facilitating the development of effective behaviour therapy (including methods based on both classical and operant conditioning).
- On the other hand, an increasingly significant ethical and legal constraint on therapeutic practice, the doctrine of *informed consent*, obliges behaviour therapists (and other practitioners in the helping professions, including psychiatry) to acknowledge the autonomy of those who come to them for help.
- The *behaviour therapist's dilemma* describes the tension between these two aspects of modern clinical psychology: either radical behaviourism is false or human beings never act autonomously. This involves having to choose between alternatives that many contemporary behaviour therapists would find difficult to defend.

(From Ringen, 1996)

Rogers, freedom and the fully functioning person

As we saw in Chapter 2, Rogers was perhaps the most influential *humanistic, phenomenological* psychologist. As such, he stressed the process of self-actualisation and the necessity of adopting the other person's perspective if we're to understand that person, and in particular, his/her self-concept (see Chapter 42).

Understanding the self-concept is also central to Rogers' client-centred therapy (see Chapter 45). His experience as a therapist convinced him that real change does occur in therapy: people choose to see themselves and their life situations differently. Therapy and life are about free human beings struggling to become more free. Personal experience is important, but it doesn't imprison us. How we react to our experience is something we ourselves choose and decide (Morea, 1990).

ASK YOURSELF...

- According to Rogers, in what ways are individuals prevented from recognising their true feelings and behaviour?
- In what respect is Rogers' view of human beings a more optimistic one than, say, Freud's?

Rogers' deep and lasting trust in human nature didn't, however, blind him to the reality of evil behaviour:

> In my experience, every person has the capacity for evil behaviour. I, and others, have had murderous and cruel impulses ... feelings of anger and rage, desires to impose our wills on others ... Whether I ... will translate these impulses into behaviour depends ... on two elements: social conditioning and voluntary choice ... (Rogers, 1982, cited in Thorne, 1992)

By making the distinction between 'human nature' and behaviour, Rogers retains his optimistic view of human beings. However, this didn't exclude altogether a deterministic element in his later writings. In *Freedom to Learn for the eighties* (1983), he states that it's becoming clear from science that human beings are complex machines and not free, and determinism 'is the foundation stone of present-day science'. So how can this be reconciled with self-actualisation, psychological growth and the freedom to choose?

One proposed solution is in the form of a version of soft determinism. Unlike neurotic and incongruent people whose defensiveness forces them to act in ways they'd prefer not to, the healthy, fully functioning person:

> ... not only experiences, but utilises, the most absolute freedom when he spontaneously, freely and voluntarily chooses and wills that which is absolutely determined.

He seemed to mean that at the same time as we *choose* our behaviour, it's also being *determined* by all the relevant conditions that exist. The open, responsive (fully functioning) person is fully aware of all that's going on inside, and has an accurate grasp of existing external factors. This individual is free, but s/he will take a particular course of action: in the presence of all available stimuli there are certain behaviours that are most productive from both subjective and objective points of view. In this sense, there's no contradiction between free will and determinism: they coincide (Nye, 2000).

Sociobiology: extreme biological determinism

Rose *et al.*'s *Not In Our Genes* (1984) is a critique of *biological determinism* in general. Here, we concentrate on those aspects that are most relevant to the issue of freedom and determinism.

The central claim of *sociobiology* is that all aspects of human culture and behaviour, like that of all animals, are coded in the genes and have been moulded by natural selection. Sociobiology is a reductionist, biological determinist explanation of human existence. Its adherents claim that:

- the details of present and past social arrangements are the inevitable manifestations of the specific action of genes
- the particular genes that lie at the basis of human society have been selected in evolution; therefore, the traits they determine result in higher reproductive fitness of the individuals that carry them (that is, they're more likely to survive to have offspring that will have genes for those traits: see Chapter 2).

If one accepts biological determinism, nothing needs to be changed:

> ... for what falls in the realm of necessity falls outside the realm of justice. The issue of justice arises only when there is choice ... To the extent that we are free to make ethical decisions that can be translated into practice, biology is irrelevant; to the extent that we are bound by our biology, ethical judgements are irrelevant ...

Biological determinism has such wide appeal because it removes guilt and responsibility: it's 'our biology' that's to blame, *not people,* either individually or collectively. But, according to Rose *et al.*, this involves a *false dichotomy* between biological and cultural/social, just as 'nature/nurture' (see Chapter 50) and 'mind/ brain' (see below) are false dichotomies. 'Free will/determinism' is another. What characterises human development and actions is that they're the product of an immense array of interacting, intersecting causes. Our actions aren't random or independent with respect to the totality of those causes as an interacting system, for we're material beings in a causal world:

> ... But to the extent that they are free, our actions are independent of any one or even a small subset of those multiple paths of causation: that is the precise meaning of freedom in a causal world. When ... our actions are predominantly constrained by a single cause, like ... the prisoner in his cell ... we are no longer free. For biological determinists we are unfree because our lives are strongly constrained by a relatively small number of internal causes, the genes for specific behaviours or for pre-disposition to those behaviours But this misses the essence of the difference between human biology and that of other organisms ... Our biology has made us into creatures who are constantly re-creating our own psychic and material environments, and whose individual lives are the outcomes of an extraordinary multiplicity of intersecting causal pathways. Thus, it is our biology that makes us free. (Rose *et al.*, 1984)

CRITICAL DISCUSSION 49.1 Freedom as an evolutionary reality

- Belief in evolutionary forces and genetic influences may lead sociobiologists largely to deny free will, but it can also lead to the opposite conclusion. According to Dennett (2003):

  Free will is an evolved creation of human activity and beliefs, and it is just as real as such other creations as music and money ... Recognising our uniqueness as reflective, communicating animals does not require any 'human exceptionalism' that must shake a defiant fist at Darwin ... We may thus concede that material forces ultimately govern behaviour, and yet at the same time reject the notion that people are always and everywhere motivated by material self-interest.

- Dennett believes that educated people are trapped in a strange kind of double-think. On the one hand, they believe that natural science implies determinism, which proves they have no control over their lives. But on the other hand, in their actual daily lives, they mostly assume they *do* have this control. But the conflict can create deep, underlying anxiety, confusion, guilt and a sense of futility. (This is basically the same dilemma faced by James: see text above.)
- Consistent with James's position, Dennett argues that determinism *isn't* fatalism, which teaches that human effort makes no difference to what happens. Fatalism is another term for *hard* determinism, which reflects the view of the mind as mere *epiphenomenona* (see text below). But fatalism is clearly false, based on an oversimplified, largely outdated scientific view of the world. All the sciences, including physics, now find complexity and variety of patterns everywhere. The more complex creatures become, the wider the range of activities open

to them. And with this increase goes a steadily increasing degree of freedom. According to Dennett:

The freedom of the bird to fly wherever it wants is definitely a kind of freedom, a distinct improvement on the freedom of the jellyfish to float wherever it floats, but a poor cousin of our human freedom ... Human freedom, in part a product of the revolution begat of language and culture, is about as different from bird freedom as language is different from birdsong. But to understand the richer phenomenon, one must first understand its more modest components and predecessors.

- This evolutionary view of human freedom is similar to that proposed by Rose (1997). Both make the central point that our conscious inner life isn't some sort of irrelevant supernatural intrusion on the working of our physical bodies (a 'ghost in the machine'), but a crucial feature of their design. We've evolved as beings that can feel and think in a way that makes us able to direct our actions. We operate as whole people, our minds and bodies are aspects of us, not separate items. They don't need to compete for the driving seat (Midgley, 2003).

REDUCTIONISM

What is reductionism?

Luria (1987) traces the origins of reductionism to the mid-nineteenth-century view within biology that an organism is a complex of organs, and the organs are complexes of cells. To explain the basic laws of the living organism, we have to study as carefully as possible the features of separate cells.

From its biological origins, reductionism was extended to science in general. For example, the properties of a protein molecule could be uniquely determined or predicted in terms of properties of the electrons or protons making up its atoms. Consistent with this view is Garnham's (1991) definition of reductionism as:

> ... the idea that psychological explanations can be replaced by explanations in terms of brain functioning or even in terms of physics and chemistry.

Although reductionism's ultimate aim (according to its supporters) is to account for all phenomena in terms of microphysics, *any* attempt to explain something in terms of its components or constituent parts may be thought of as reductionist. A useful definition, which is consistent with this broader view, is that of Rose *et al.* (1984), for whom reductionism is:

> ... the name given to a set of general methods and modes of explanation both of the world of physical objects and of human societies. Broadly, reductionists try to explain the properties of complex wholes – molecules, say, or societies – in terms of the units of which those molecules or societies are composed.

Rose (1997) identifies four major types of reductionism (or different meanings of the term).

Box 49.6 Different meanings of reductionism

- **Reductionism as methodology:** This refers to the attempt to isolate variables in the laboratory in order to simplify the living world's enormous complexity, flux, and multitude of interacting processes. This is the basis of the experiment, which reflects natural science's attempt to identify *cause-and-effect* relationships (see Chapter 3).
- **Theory reduction:** This refers to science's aim to capture as much of the world in as few laws or principles as possible. It's related to philosophical reductionism.

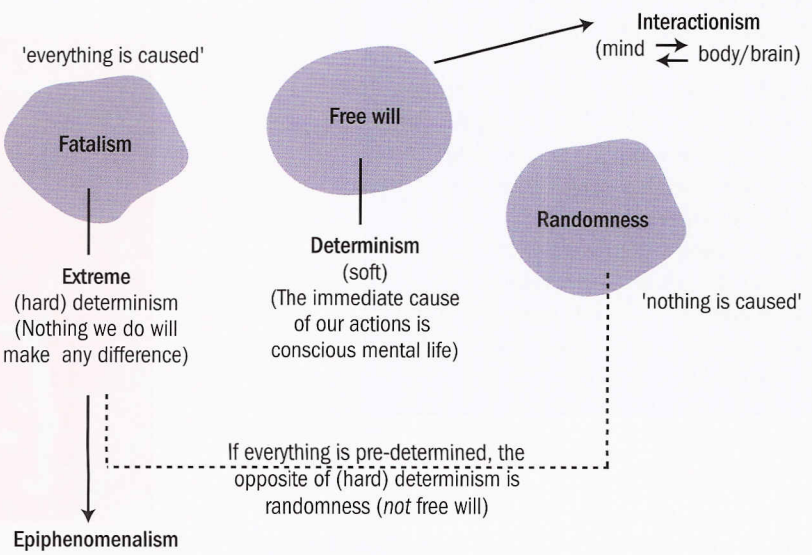


Figure 49.1 The relationship between free will and determinism, showing the link with theories of the mind–brain relationship

- **Philosophical reductionism:** This refers to the belief that because science is unitary, and because physics is the most fundamental of the sciences, ultimately all currently separate disciplines (including psychology) will be 'reduced' to physics (see the quotes from Garnham, 1991, above, and Crick, 1994, page 897).
- **Reductionism as ideology:** This refers to the very marked tendency in recent years to identify genes responsible for a whole range of complex human behaviours, including stress, anxiety, depression, personality, homosexuality, intelligence, alcoholism, criminality and violence.

(Based on Rose, 1997)

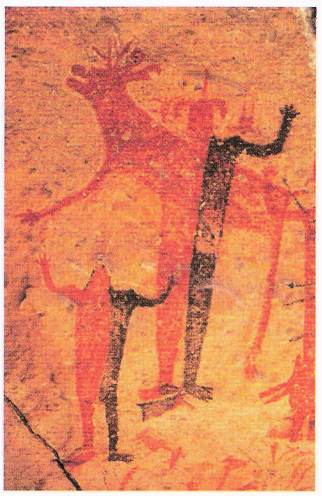
Rose calls the claim that there's a direct causal link between genes and behaviour *neurogenetic determinism*. It involves a sequence of (false) assumptions and arguments, one of which is the dichotomy between genetic and environmental causes (or nature and nurture: see Chapter 50).

ASK YOURSELF...

- There are many examples of psychological theories and concepts that fit either or both of Garnham's and Rose *et al.*'s definitions. These can be found in all areas of psychology, but below are a few of the more 'obvious' examples. For each one, try to explain (a) why the theory or concept is reductionist, and (b) what the strengths and/or weaknesses of such an approach are.

(i) According to *structuralism* (e.g. Wundt), perception is simply a series of sensations (see Chapter 3).
(ii) According to Watson's *peripheralism*, thought consists of tiny movements of the vocal chords (see Chapter 18).
(iii) *Intelligence* is a person's performance on a standardised intelligence test (his/her IQ score: see Chapter 41).
(iv) *Psychological sex differences* are caused by biological factors (such as hormones: see Chapter 36).
(v) According to Freud, *personality development* involves progress through a series of *psychosexual stages* (see Chapter 35).
(vi) *Schizophrenia* is caused by an excess of the neurotransmitter *dopamine* (see Chapter 44).
(vii) According to Adorno *et al.*, anti-semitism (and other forms of racism) are symptomatic of the *authoritarian personality* (see Chapter 25).

The mind–body problem



Perhaps the oldest and most frequently debated example of reductionism is the *mind–body problem* (or the *problem of mind and brain*). Originally a philosophical issue, it continues to be discussed, often passionately, by neurophysiologists, biologists, neuropsychologists, and psychologists in general.

It's generally agreed that the mind (or consciousness) is a property of human beings (as is walking upright on two legs), and that without the human brain there'd be no consciousness. But a 'problem' remains.

Box 49.7 The problem of the mind–brain relationship

- How can two 'things' be related when one of them is physical (the brain has size, weight, shape, density, and exists in space and time) and the other apparently lacks all these characteristics?
- How can something non-physical/non-material (the mind) influence or produce changes in something physical (the brain/body)?
- The 'classic' example given by philosophers to illustrate the problem is the act of deciding to lift one's arm. (This example also illustrates the exercise of [free] will: see text above.) From a strictly scientific perspective, this kind of causation should be impossible. Science (including psychology and neurophysiology) has traditionally rejected any brand of *philosophical dualism:* the belief in the existence of two essentially different kinds of 'substance', the physical body and the non-physical mind (see Box 49.8, page 897).

From an *evolutionary* perspective, could consciousness have equipped human beings with survival value unless it had causal properties (Gregory, 1981); that is, unless it could actually bring about changes in behaviour? Our subjective experiences tell us that our minds do affect behaviour, and that consciousness does have causal properties (just try lifting your arm). However, many philosophers and scientists from various disciplines haven't always shared the lay person's common-sense understanding.

Self-awareness/consciousness and the ability to understand and predict others' behaviour may be the characteristics of human beings which make them unique as a species

While there are many theories of the mind–brain relationship, most aren't strictly relevant to the debate about reductionism. Box 49.8 and Figure 49.2 summarise most of the major theories, but emphasis is given to reductionist approaches, especially as they impinge on psychological theories.

Box 49.8 Some major theories of the mind–brain relationship

- Theories fall into two main categories: *dualism* (which distinguishes between mind and brain), and *monism* (which claims that only mind or matter are real).
- According to Descartes' seventeenth-century dualist theory (which first introduced the mind–body problem into philosophy), the mind can influence the brain, but not vice versa. While *epiphenomenology* sees the mind as a kind of by-product of the brain (the mind has no influence on the brain), *interactionism* sees the influence as two-way.
- *Psychophysical parallelists* are dualists who believe that there's no mind–brain interaction at all: mental and neural events are merely perfectly *synchronised or correlated*.
- According to *mentalism/idealism,* only mental phenomena are real. *Phenomenological* theories, such as that of Rogers, and *constructionist* explanations of behaviour, have a mentalist 'flavour'.
- Most monist theories take one or other form of *materialism*.
- The *peripheralist* version of materialism is illustrated by Skinner's *radical behaviourism* (see Chapter 2). During the 1930s, Skinner denied the existence of mental phenomena (as had Watson, the founder of behaviourism). However, from 1945 he began to adopt a less extreme view, recognising their existence, but defining them as *covert/internal actions,* subject to the same laws of conditioning as overt behavioural events. This is a form of reductionism.
- *Centralist materialism* (or *mind–brain identity theory*) identifies mental processes with purely physical processes in the central nervous system. While it's logically possible that there might be separate, mental, non-physical phenomena, it just turns out, as a matter of fact, that mental states are identical with physical states of the brain. We are, simply, very complicated *physico-chemical mechanisms.*
- *Eliminative materialism* represents an extreme reductionist form of (centralist) materialism (see text below).

(Based on Flanagan, 1984; Gross, 2003b; Teichman, 1988)

ASK YOURSELF...

- Using your knowledge of *biopsychology,* try to relate the examples below to the theories outlined in Box 49.8 and Figure 49.2.
- Specifically, do these examples involve interactions between mind and brain, and, if so, in what direction is the influence taking place?
  - (a) the effects of psychoactive drugs (see Chapters 8 and 45)
  - (b) electrical stimulation of the brain (see Chapter 4)
  - (c) Sperry's study of split-brain patients (see Chapter 4)
  - (d) stress (see Chapter 12)
  - (e) placebo effects (see Chapter 45)

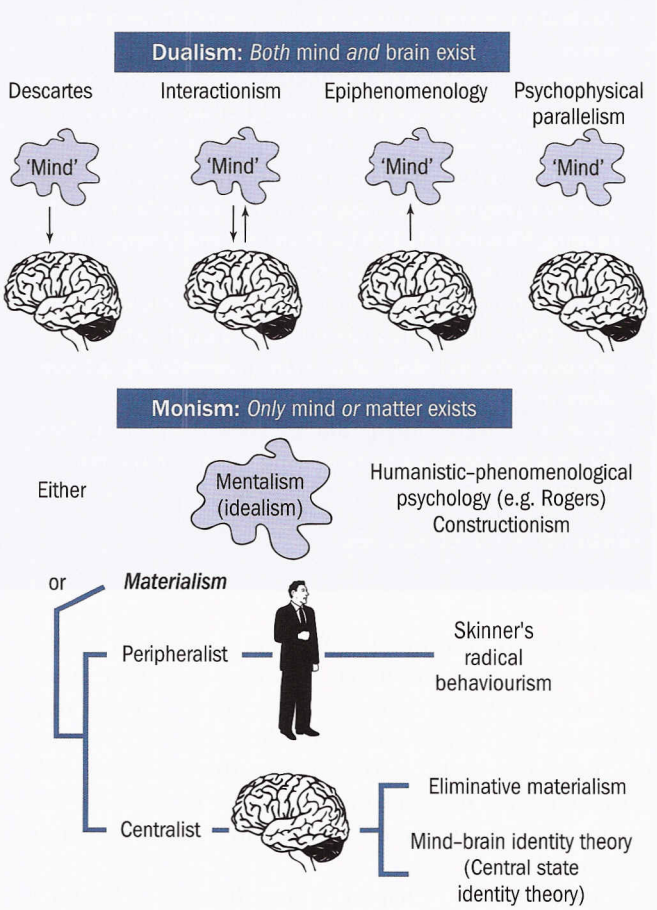


Figure 49.2 An outline of the major theories of the mind–brain relationship

Reductionist theories of the mind–brain relationship

As Box 49.8 shows, *eliminative materialism* is an extreme form of reductionist materialism. What makes it reductionist is the attempt to *replace* a psychological account of behaviour with an account in terms of neurophysiology. An example of this approach is Crick's (1994) *The Astonishing Hypothesis: The Scientific Search for the Soul.* According to Crick:

> You, your joys and your sorrows, your memories and your ambitions, your sense of personality and free will, are in fact no

more than the behaviour of a vast assembly of nerve cells and their associated molecules.

But is this a valid equation to make? According to Smith (1994), the mind and brain problem is radically different from other cases of *contingent identity* (identical as a matter of fact) with which it's usually compared, such as 'a gene is a section of the DNA molecule'. What's different is reductionism, and the related issue of exactly what's meant by *identity.*

Box 49.9 Different meanings of 'identity' relevant to the mind–brain relationship

- While it's generally agreed that we cannot have a mind without a brain, mind states and brain states *aren't* systematically correlated, and the neurophysiological and neurological evidence points towards *token identity.*
- For example, we cannot just assume that the same neurophysiological mechanisms will be used by two different people both engaged in the 'same' activity of reading (Broadbent, 1981). There are many ways that 'the brain' can perform the same task.
- But it's precisely this kind of systematic correlation that mind–brain identity has been taken to imply, whereby whenever a mind state of a certain type occurs, a brain state of a certain type occurs (*type identity*).
- Token identity means that there must always be a place for an autonomous psychological account of human thought and action.

(Based on Harré *et al.*, 1985)

According to Penrose (1990), there's a built-in *indeterminacy* in the way individual neurons and their synaptic connections work (their responses are inherently unpredictable). Yet, despite this unpredictability at the level of the individual units or components, the system as a whole is predictable. The 'nervous system' (or subsystems within it) doesn't operate randomly, but in a highly organised, structured way.

Consciousness (Chapter 7), intelligence (Chapter 41), and memory (Chapter 17) are properties of the brain as a system, *not* properties of the individual units, and they couldn't possibly be predicted from analysing the units. Instead, they 'emerge' from interactions between the units that compose the system (and so are called *emergent properties*). The whole is greater than the sum of its parts (Rose, 1997: see Chapter 15).

Can you be a materialist without being a reductionist?

According to Rose (1992):

The mind is never replaced by the brain. Instead we have two distinct and legitimate languages, each describing the same unitary phenomena of the material world.

Rose speaks as a materialist and an *anti-reductionist,* who believes that we should learn how to translate between mind language and brain language (although this may be impossibly difficult: see Box 49.6). While most materialists are also reductionists, and vice versa, this isn't necessarily so. Freud, for example, was a materialist who believed that no single scientific vocabulary (such as anatomy) could adequately describe (let alone explain) all facets of the material world. He believed in the *autonomy of psychological explanation.*

The fact that there are different 'languages' for describing minds and brains (or different levels of description or universes of discourse) relates to the question of the relevance of knowing, say, what's going on inside our brains when we think or are aware. For Eiser (1994):

The firing of neurons stands to thought in the same relation as my walking across the room (etc.) stands to my getting some coffee. It is absolutely essential in a causal or physical sense, and absolutely superfluous ... to the logic of the higher-order description. In short, I can accept that it happens, and then happily ignore it.

This explains how it's possible to be simultaneously a materialist (the brain is necessarily implicated in everything we do and the mind doesn't represent a different kind of reality) and an anti-reductionist (we can describe and explain our thinking without having to 'bring my brain into it'). Two separate levels of description are involved.

CONCLUSIONS

Given psychology's intellectual and historical roots in philosophy and natural science, it's hardly surprising that psychological theories have contributed to the debate about free will versus determinism, and reductionism. The possession of free will is a fundamental aspect of our common-sense concept of a person. Therefore, any theory calling itself psychological must have something to say about this issue.

Equally, belief (or not) in the independence of psychological from neurophysiological explanations of behaviour is crucial to the survival of psychology itself as a separate discipline. According to Hegarty (2000), *psychoneuroimmunology* (which we discussed in Chapter 12 in relation to stress) offers a:

... middle ground for mind–body monists and dualists to meet upon. Scientific research has given us insight into the complex realm of psychophysiology – the interface ... between body and mind and in which the emotions figure large ...

CHAPTER SUMMARY

- Our intuitive belief in **free will** conflicts with the scientific belief in **determinism**. While free will implies having a mind, the things we do with our minds may themselves be determined.
- Free will is an ambiguous concept and can denote **having a choice**, **not being coerced** or **constrained**, **voluntary behaviour**, and **deliberate control.** The more automatic our behaviours, the weaker our subjective experience of freedom becomes.
- Stimulation of the brains of conscious patients supports the view that free will is part of our experience of being a person. This is demonstrated by **psychological reactance** and **intrinsic motivation/self-determination**.
- Definitions of abnormality, and the diagnosis/treatment of mental disorders, often involve judgements about free will. **Diminished responsibility** is a legally acceptable defence (for murder).
- James distinguished between **soft** and **hard determinism**, the former allowing **conscious mental life** (CML) to be the immediate cause of behaviour.
- Freud extended the law of determinism to mental phenomena (**psychic determinism**). His concept of **overdetermination** allows the conscious mind a role in influencing behaviour, and he often tried to interpret the **meaning** of patients' thoughts and behaviours (rather than looking for causes).
- Skinner's **radical behaviourism** involves a rejection of **explanatory fictions**, such as free will and other mentalistic terms. The **illusion of free will** survives because the environmental causes of behaviour are often hidden from us.
- Rogers stressed self-actualisation, psychological growth, and the freedom to choose. But he also argued that science shows people to be complex machines and not free. The **fully functioning person** chooses to act the way s/he must.
- **Sociobiologists**, by explaining all individual and social behaviour in terms of genes selected through evolution, seem to deny guilt and responsibility. But this involves a **false dichotomy** between biological and cultural/social.
- According to Rose *et al.*, what makes humans unique is that our biology has made us into creatures who are constantly re-creating our own psychic and material environments.
- According to Dennett, determinism isn't the same as **fatalism**, and conscious life is a crucial **design feature** of human beings.
- Although the ultimate aim of **reductionism** is to account for all phenomena (including psychological) in terms of microphysics, **any** attempt to explain something in terms of its components is reductionist.
- Rose identifies reductionism as **methodology**, **theory reduction**, **philosophical** and **ideology** (**neurogenetic determinism**).
- From a strictly **scientific** perspective, it should be impossible for a non-physical mind to influence the physical brain. However, from an **evolutionary** perspective, consciousness should be able to produce behaviour change.
- Theories of the **mind–brain relationship** are either **dualist** or **monist**. Dualist theories include Descartes' original dualism, **epiphenomenology**, **interactionism** and **psychophysical parallelism**.
- Monist theories include **mentalism/idealism**, **peripheralist materialism** (such as Skinner's radical behaviourism) and **centralist materialism/mind–brain identity theory.**
- Skinner's definition of mental phenomena as **covert/internal actions** is reductionist, as is **eliminative materialism**. The latter confuses **type** with **token identity**.
- **Emergent properties** (such as intelligence and consciousness) reflect the activity of the brain as a **system** and couldn't possibly be predicted from analysis of its components.
- While most materialists are also reductionists, some argue that psychology and neurophysiology constitute distinct **levels of description/universes of discourse,** which cannot replace each other. Freud, for example, believed in the **autonomy of psychological explanation**.

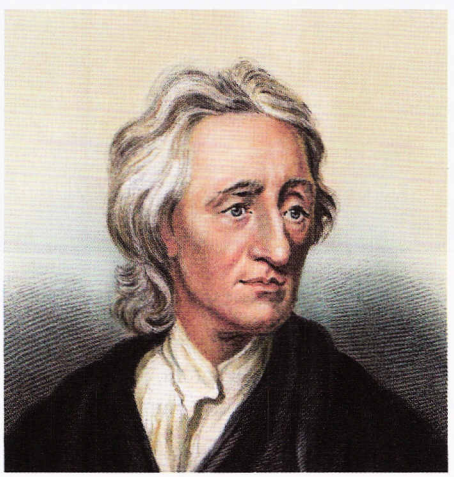
NATURE AND NURTURE

INTRODUCTION AND OVERVIEW



The debate concerning the influence of nature and nurture (or heredity and environment) on human behaviour is one of the longest-running, and most controversial, both inside and outside psychology. It deals with some of the most fundamental questions that human beings (at least those from western cultures) ask about themselves, such as 'How do we come to be the way we are?' and 'What makes us develop in the way we do?'

These and similar questions have been posed (sometimes explicitly, sometimes implicitly) throughout this book in relation to a wide range of topics. These include perceptual abilities (Chapter 16), language acquisition (Chapter 19), aggression (Chapter 29), attachment (Chapter 32), gender development (Chapter 36), intelligence (Chapter 41), and schizophrenia and depression (Chapter 44). In some of these examples, (such as language and perception) the focus of the debate is on an ability shared *by all human beings,* while in others (such as intelligence and schizophrenia) the focus is on *individual differences.*

In both cases, however, certain assumptions are made about the exact meaning of 'nature' and 'nurture', as well as about how they're related. By distinguishing different types of environment, such as *shared* and *non-shared,* it's easier to understand the relationship between nature and nurture, including *gene–environment correlation* and *gene–environment interaction.*

NATIVISM, EMPIRICISM AND INTERACTIONISM

Nativism is the philosophical theory according to which knowledge of the world is largely innate or inborn: nature (heredity) is seen as determining certain abilities and capacities. The French philosopher Descartes was a seventeenth-century nativist theorist who, as we noted in Chapter 3, had an enormous impact on science in general, including psychology. At the opposite philosophical extreme is *empiricism,* associated mainly with seventeenth-century British philosophers, and even more influential on the development of psychology. A key empiricist was Locke, who believed that at birth the human mind is a *tabula rasa* (or 'blank slate'). This is gradually 'filled in' by learning and experience.

John Locke (1632–1704)

ASK YOURSELF...

- Try to identify psychological (and other) theories that adopt an *extreme* position regarding the nature–nurture issue.
- Which particular features of the theories made you classify them in this way?

Nativism and empiricism are extreme theories in that they were trying to answer the question 'Is it nature or nurture?', as if only one or the other could be true. Early psychological theories tended to reflect these extremes, as in Gesell's concept of *maturation* and Watson's *behaviourism.*

Box 50.1 Gesell and Watson: two extreme viewpoints

- According to Gesell (1925), one of the American pioneers of developmental psychology, *maturation* refers to genetically programmed patterns of change. The instructions for these patterns are part of the specific hereditary information passed on at the moment of conception (Bee, 2000). All individuals will pass through the same series of changes, in the same order, making maturational patterns *universal* and *sequential*. They're also 'relatively impervious to environmental influence'.
- Gesell was mainly concerned with infants' psychomotor development (such as grasping and other manipulative skills), and locomotion (such as crawling and walking). These abilities are usually seen as 'developing by themselves', according to a genetically determined timetable. Provided the baby is physically normal, practice or training aren't needed – the abilities just 'unfold'.
- For Watson (1925), environmental influence is all-important (see Chapters 2 and 3), and human beings are completely malleable:

  Give me a dozen healthy infants, well-formed, and my own specialised world to bring them up in and I'll guarantee to take any one at random and train him to become any type of specialist I might select – a doctor, lawyer, artist, merchant-chief and, yes, even beggar-man and thief, regardless of his talents, penchants, abilities, vocations and race of his ancestors.

- Watson (1928) also claimed that there's no such thing as an inheritance of capacity, talent, temperament, mental constitution and character:

  The behaviourists believe that there is nothing from within to develop. If you start with the right number of fingers and toes, eyes, and a few elementary movements that are present at birth, you do not need anything else in the way of raw material to make a man, be that man genius, a cultured gentleman, a rowdy or a thug.

ASK YOURSELF...

- Try to identify psychological theories and areas of research in which the process of maturation plays an important role. Examples are most likely to be found in developmental psychology.

The concept of maturation continues to be influential within psychology. Not only does maturation explain major biological changes, such as puberty (see Chapter 37) and physical aspects of ageing (see Chapter 39), but all stage theories of development assume that maturation underpins the universal sequence of stages. Examples include Freud's *psychosexual theory* (see Chapter 35), Erikson's *psychosocial theory* (see Chapters 37, 38 and 39), and Piaget's *theory of cognitive development* (see Chapter 34). Watson's extreme empiricism (or *environmentalism*) was adopted in Skinner's *radical behaviourism*, which represents a major model of both normal and abnormal behaviour (see Chapters 2 and 45).

Are nativism and empiricism mutually exclusive?

As noted in Box 50.1, maturationally determined developmental sequences occur regardless of practice or training. However, as Bee (2000) points out:

> These powerful, apparently automatic maturational patterns require at least some minimal environmental support, such as adequate diet and opportunity for movement and experimentation.

At the very least, the environment must be *benign*, that is, it mustn't be harmful in any way, preventing the ability or characteristic from developing. More importantly, the ability or characteristic cannot develop without environmental 'input'. For example, the possession of a language acquisition device (LAD) as proposed by Chomsky (1965: see Chapter 19) must be applied to the particular linguistic data provided by the child's linguistic community, so the child will acquire only *that* language (although it could just as easily have acquired *any* language). This is an undeniable fact about language acquisition, which Chomsky himself recognised.

Another example of the role of the environment involves vision. One of the proteins required for development of the visual system is controlled by a gene whose action is triggered only by visual experience (Greenough, 1991). So some visual experience is needed for the genetic programme to operate. Although every (sighted) child will have some such experience under normal circumstances, examples like these tell us that maturational sequences don't simply 'unfold'. The system appears to be 'ready' to develop along particular pathways, but it requires experience to trigger the movement (Bee, 2000).

Another way of considering the interplay between nature and nurture is to look at Freud's and Piaget's developmental theories. Although maturation underlies the sequence of stages in both theories, the role of experience is at least as important.

Box 50.2 Nature and nurture in Freud's and Piaget's developmental theories

- For Freud it's not the sexual instinct itself that matters, but rather the reactions of significant others (especially parents) to the child's attempts to satisfy its sexual needs. Both excessive frustration and satisfaction can produce long-term effects on the child's personality, such as fixation at particular stages of development (see Box 35.1, page 603). This makes him an *interactionist*:

  The constitutional factor must await experiences before it can make itself felt; the accidental factor must have a constitutional basis in order to come into operation ... (Freud, 1905b/1953b, in Miller, 2002)

  The demands of civilisation are as real as the demands of the body.
- Although Freud is commonly referred to as an instinct theorist (suggesting that he was a nativist), his concept of an instinct was very different from the earlier view of unlearned, largely automatic (pre-programmed) responses to specific stimuli (based on non-human species: see Chapter 9). Instead of using the German word '*Instinkt*', he used '*Trieb*' (drive), which denotes a relatively undifferentiated form of energy capable of almost infinite variation through experience (see Box 2.2, page 19).
- As a biologist, Piaget stressed the role of *adaptation* to the environment. This involves the twin processes of *assimilation* and *accommodation*, which in turn are related to (dis-)equilibration (see Chapter 34). These mechanisms are part of the biological 'equipment' of human beings, without which their intelligence wouldn't change (the individual wouldn't progress through increasingly complex stages of development).
- However, the infant actively explores its environment and constructs its own knowledge and understanding of the world (the child as scientist: Rogoff, 1990). According to Piaget (1970), intelligence consists:

  ... neither of a simple copy of external objects nor of a mere unfolding of structures preformed inside the subject, but rather ... a set of structures constructed by continuous interaction between the subject and the external world.

Both Freud's and Piaget's theories demonstrate that:

> There is a trade-off in nature between pre-specification, on the one hand, and plasticity, on the other, leading ultimately to the kind of flexibility one finds in the human mind ... (Karmiloff-Smith, 1996)

Maturation is an example of what Karmiloff-Smith means by 'pre-specification', and inborn biases represent

Annette Karmiloff-Smith

another example. For example, very young babies already seem to understand that unsupported objects will fall (move downward), and that a moving object will continue to move in the same direction unless it encounters an obstacle (Spelke, 1991: see Chapter 16). However, these 'pre-existing conceptions' are merely the beginning of the story. What then develops is the result of experience filtered through these initial biases, which constrain the number of developmental pathways that are possible (Bee, 2000).

Both Freud and Piaget focused on interaction between biological maturation and experience with the physical world (especially Piaget) and the social world (especially Freud). Bandura's theory of *triadic reciprocal causation* (e.g. Bussey & Bandura, 1999) adds the person's *behaviour* to the interaction: one's behaviour can *change* the environment.

According to Bee, no developmental psychologists today would take the 'Is it nature or nurture?' form of the debate seriously. Essentially, every facet of a child's development is a product of some pattern of interaction between the two. Until fairly recently, however, the theoretical pendulum was well over towards the nurture/environmental end of the continuum. In the last decade or so, there's been a marked swing back towards the nature/biological end, partly because of the impact of sociobiology and its more recent off-shoot evolutionary psychology (see Chapter 2).

ASK YOURSELF...

- Draw a diagram, representing a continuum, with 'extreme nativism' (nature) at one end and 'extreme empiricism' (nurture) at the other.
- Now place theories along the continuum to indicate the emphasis they give to either nature or nurture – or both.
- The theories can be drawn from any area of psychology. They're likely to include those identified in the first 'Ask Yourself ...', but should also reflect the approaches discussed in Chapter 47. (Some examples are given in Figure 50.3, page 905.)

What do we mean by 'nature'?

In the *Introduction and overview*, we noted that some examples of the nature–nurture debate involve abilities or capacities common to all human beings (such as language and perception), while others involve individual differences (such as intelligence and schizophrenia). According to Plomin (1994), it's in the latter sense that the debate 'properly' takes place, and much of the rest of this chapter will reflect the 'individual differences' approach.

Within *genetics* (the science of heredity), 'nature' refers to what's typically thought of as inheritance, that is, differences in genetic material (chromosomes and genes) transmitted from generation to generation (from parents to offspring). The 'father' of genetics, Gregor Mendel (1895), explained the difference between different genes in terms of smooth and wrinkled seeds in garden peas. Similarly, modern human genetics focuses on genetic differences between individuals, reflecting the use of the word 'nature' by Galton, who coined the phrase nature–nurture in 1883 as it's used in the scientific arena (Plomin, 1994).

Gregor Mendel (1822–1884)

So, what are genes? Genes are the basic unit of hereditary transmission, consisting of large molecules of deoxyribonucleic acid (DNA). These are extremely complex chemical chains, comprising a ladder-like, double helix structure (discovered by Watson & Crick in 1953: see Figure 50.1).

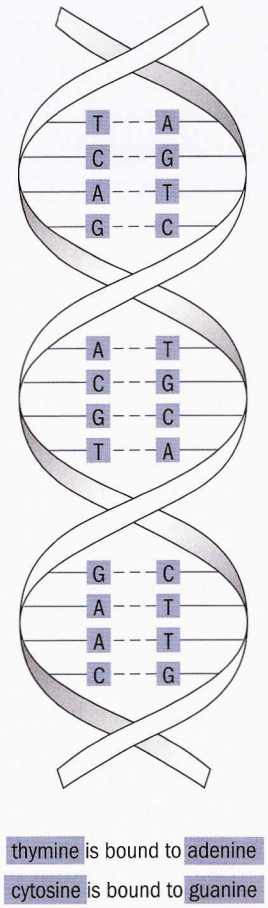


Figure 50.1 The structure of a DNA molecule represented schematically. This shows its double-stranded coiled structure and the complementary binding of nucleotide bases, guanine (G) to cytosine (C) and adenine (A) to thymine (T)

The genes, which occur in pairs, are situated on the chromosomes, which are found within the nuclei of living cells. The normal human being inherits 23 pairs of chromosomes, one member of each pair from each parent. The twenty-third pair comprises the sex chromosomes, which are two Xs in females, and an X and a Y in males (see Chapter 36 and Figure 50.2).

The steps of the gene's double helix (or 'spiral staircase': Plomin, 1994) consist of four nucleotide bases (adenine, thymine, cytosine, and guanine). These can occur in any order on one side of the double helix, but the order on the other side is always fixed, such that adenine always pairs with thymine, and cytosine always pairs with guanine. Taking just one member of each of the 23 pairs of chromosomes, the human *genome* comprises more than three billion nucleotide base pairs (Plomin, 1994). Two major functions of genes are *self-duplication* and *protein synthesis.*

Self-duplication

DNA copies itself by unzipping in the middle of the spiral staircase, with each half forming its complement: when a cell divides, all the genetic information (chromosomes and genes) contained within the cell nucleus is reproduced. This means that the 'offspring' cells are identical to the 'parent' cells (*mitosis*), but this process applies only to *non-gonadal* (non-reproductive) cells (such as skin, blood, and muscle cells).

The reproductive (or *germ*) cells (ova in females, sperm in males) duplicate through *meiosis,* whereby each cell contains only half the individual's chromosomes and genes. Which member of a chromosome pair goes to any particular cell seems to be determined randomly. The resulting germ cells (*gametes*), therefore, contain 23 chromosomes, one of which will be either an X (female) or a Y (male). When a sperm fertilises an ovum, the two sets of chromosomes combine to form a new individual with a full set of 46 chromosomes.

Protein synthesis

The 'genetic code' was 'cracked' in the 1960s. Essentially, DNA controls the production of ribonucleic acid (RNA) within the cell nucleus. This 'messenger' RNA moves outside the nucleus and into the surrounding cytoplasm, where it's converted by ribosomes into sequences of amino acids, the building blocks of proteins and enzymes.

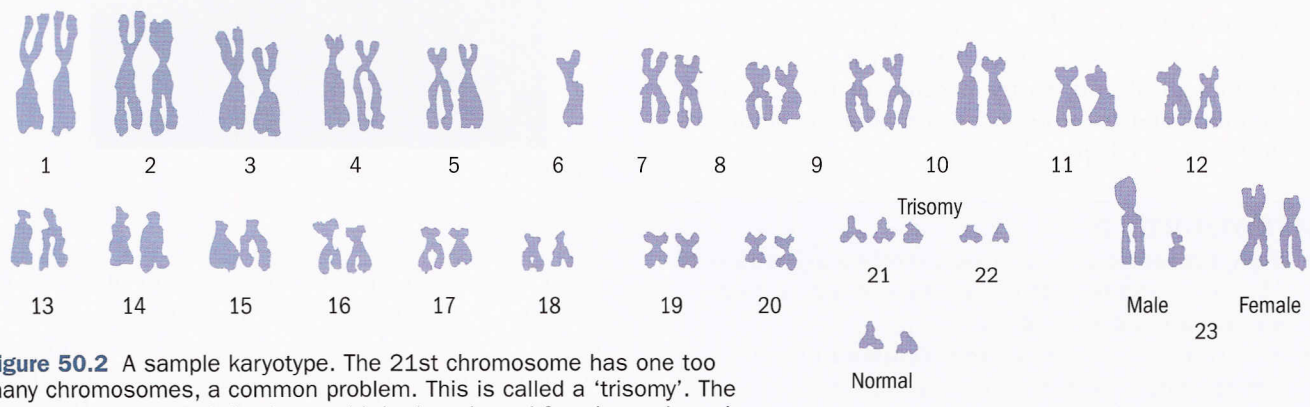

Figure 50.2 A sample karyotype. The 21st chromosome has one too many chromosomes, a common problem. This is called a 'trisomy'. The 23rd chromosome pair is shown with both male and female versions. In a normal karyotype, only one such pair would be found

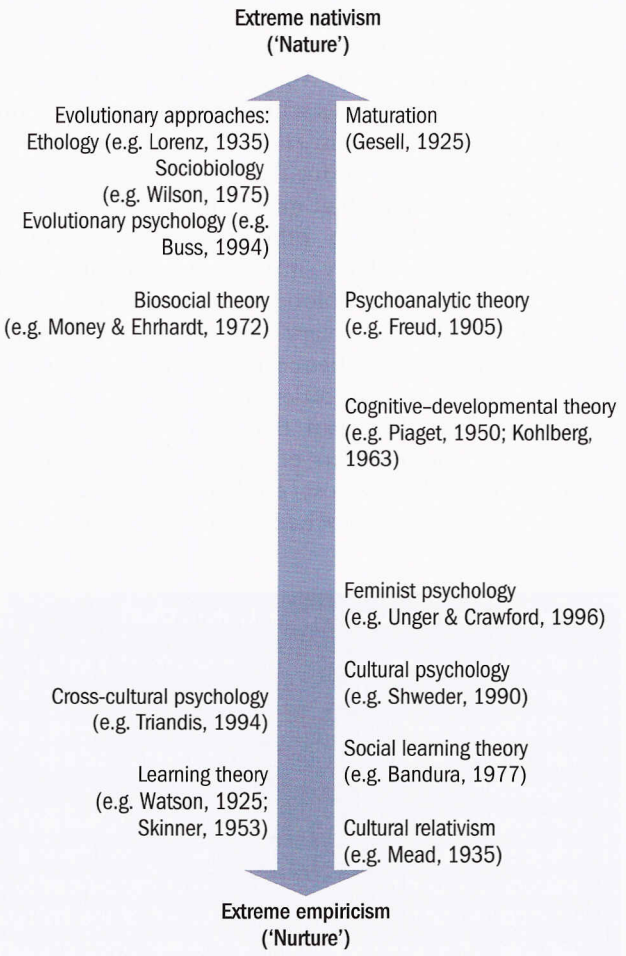

Figure 50.3 A continuum representing the position of various psychological (and other) theories on the nature–nurture debate

Genes that code for proteins and enzymes are called *structural* genes, and they represent the foundation of classical genetics (Plomin, 1994). The first single-gene disorders discovered in the human species involved metabolic disorders caused by *mutations* (spontaneous changes) in structural genes. A much-cited example is phenylketonuria, which is discussed in relation to gene–environment interaction (see below, page 909).

Most genes are *regulator* genes, which code for products that bind with DNA itself and serve to regulate other genes. Unlike the structural genes which are 'deaf' to the environment, the regulator genes communicate closely with the environment and change in response to it (Plomin, 1994).

Neurogenetic determinism: are there genes 'for' anything?

Several claims have been made in recent years about the discovery of genes 'for' a wide range of complex human behaviours (*reductionism as ideology:* Rose, 1997). Related to this is what Rose calls *neurogenetic determinism,* the claim that there's a direct causal link between genes and behaviour. This involves the false assumption that causes can be classified as *either* genetic *or* environmental, and there are additional reasons for doubting the validity of neurogenetic determinism.

Objections to neurogenetic determinism

ASK YOURSELF...
- Try to formulate some arguments against neurogenetic determinism.

- The phrase 'genes for' is a convenient, but misleading, shorthand used by geneticists. In the case of eye colour, for example (which, from a genetic point of view, is one of the more simple characteristics – or phenotypes), there's a difference in the biochemical pathways that lead to brown and to blue eyes. In blue-eyed people, the gene for a particular enzyme (which catalyses a chemical transformation en route to the synthesis of the pigment) is either missing or non-functional for some reason. A gene 'for blue eyes' now has to be reinterpreted as meaning 'one or more genes in whose absence the metabolic pathway that leads to pigmented eyes terminates at the blue-eye stage' (Rose, 1997).
- More generally, genes *don't* cause behaviour. They're chemical structures that have chemical effects on the body, and so influence behaviour through their effects on the body's response to the environment. So there are *no* genes 'for', say, neuroticism (N), although there's plenty of evidence that N is genetically influenced (such as inheriting a nervous system that's particularly sensitive to stress). Similarly, there are *no* genes 'for' alcoholism, but genetic factors may in some way affect the body's sensitivity to alcohol:

  ... Thus all relationships between genes and behaviour are of an indirect and not a direct nature ... (Schaffer, 2004)

- Claridge & Davis (2003) make the point like this:

  ... Genes code for very precise, literally microscopic, bits of biological material (proteins) that are both physically and conceptually very distant from the complex behavioural and psychological characteristics which they are supposed to – and perhaps in some sense do – influence. But it is unlikely that there are genes, or sets of genes, 'for' impulsivity, the preference for gay relationships, religiosity, anxiety, or even serious mental disorders, such as schizophrenia. The route from genes to behaviour is likely to be much more tortuous than that and, for any particular characteristic, to involve a multitude of genes and interactions among them – as well as an interplay between genes and environmental factors ...

- The search for genes that 'cause' specific behaviours or characteristics is called *molecular genetic research* (MGR). According to Joseph (2003), there are two major

reasons why we *shouldn't* expect MGR in psychiatry or psychology to provide much useful information – now or in the future:

1. it presupposes that family, twin and adoption studies have demonstrated the role of genetic factors; the serious limitations of these methods are discussed in Chapter 41
2. proponents of MGR claim that techniques such as gene therapy can be used to prevent or cure diseases influenced by identified genes; this is a commendable goal, but does society wish to use this technology to alter 'intelligence genes' or those associated with unpleasant personalities?

CRITICAL DISCUSSION 50.1 The ethics of MGR

- It's understandable that researchers would want to alleviate the suffering of those with, say, schizophrenia to help restore them to productive lives. But even if we accept the behaviour genetic argument that genes exert an important influence on behaviour and IQ differences, we could still question the necessity of trying to identify the genes involved.
- According to Plomin *et al.* (1997):

  Psychology is at the dawn of a new era in which molecular genetic techniques will revolutionize genetic research in psychology by identifying specific genes that contribute to genetic variance for complex dimensions and disorders ... The breathtaking pace of molecular genetics ... leads us to predict that psychologists will routinely use DNA markers as a toll in their research to identify some of the relevant genetic differences among individuals.

- But although behaviour genetic researchers continue to look for 'IQ genes', Joseph (2003) believes the search has been unsuccessful. Despite this failure, Plomin (1999) expects that he'll eventually succeed, and that he'll find genetic differences along race and social class lines. For Joseph:

  ... The point is not whether group differences in intelligence genes will be found – they won't – but rather the cavalier way in which investigators minimize the potential social impact of their research. Would Plomin have the same attitude if his research, for example, found that more Jews than non-Jews had ... [genes] ... associated with greed? Wouldn't there be a justifiable uproar that such research was even being done?

  We've just identified another example of *socially sensitive research* (SSR) (see Chapter 48).

◎ MGR also presupposes that the phenotypes (whether mental disorders or intelligence) are 'real' and can be reliably and validly identified and measured. But how can, for example, 'schizophrenia susceptibility genes' (in reality, a mere association between 'schizophrenia' and genetic *markers* – not the same as finding an actual gene) be found when American psychiatrists cannot 'figure out who really is schizophrenic or what schizophrenia really is' (DeLisi *et al.*, 2002, in Joseph, 2003)?

◎ As more is learned about the human genome, geneticists come to realise that many supposedly 'single-gene disorders' result from different gene mutations in different people. They may show a similar clinical picture, such as high blood cholesterol levels with an enhanced risk of coronary heart disease. However, the gene mutation, and hence the enzyme malfunction, that results in the disorder may be very different in each case. This also means that a drug which effectively treats the condition in one person may simply not work in another, whose cholesterol accumulation is caused by different biochemical factors (Rose, 1997).

Box 50.3 Is there more to heredity than DNA?

- Cells not only inherit genes, they also inherit a set of instructions that tell the genes when to become active, in which tissue, and to what extent. Without this '*epigenetic*' instruction manual, multicellular organisms would be impossible.
- Every cell, whether a liver or skin cell, inherits exactly the same set of genes. However, the manual has different instructions for different cell types, allowing the cell to develop its distinctive identity. It seems that the instruction manual is wiped clean during the formation of germ cells, ensuring that all genes are equally available, until the embryo begins to develop specific tissues. However, there's evidence to suggest that changes in the epigenetic instruction manual can sometimes be passed from parent to offspring.
- For example, pregnant women facing the brunt of the Nazi siege of the Netherlands at the end of World War II were reduced to near starvation. Some miscarried, but if they successfully gave birth, their babies appeared quite normal after a period of catch-up growth, and seemed no different from their better-nourished peers when tested at age 18.
- Many of these war babies now have children of their own (the grandchildren of the war-time pregnant mothers). Even girls who'd themselves been of normal weight at birth produced babies who were either underweight or grew into small adults, despite the post-war generation being well fed. Thus, there's a sort of 'sleeper effect', whereby the effects of starvation skipped a generation.
- Such 'awkward' findings are very difficult for geneticists to explain. However, one possible explanation is in the form of an epigenetic phenomenon called 'imprinting'. Genes exist in pairs, and they behave in exactly the same way regardless of which parent they come from. But in some cases an imprinted gene is activated only if it

comes from the father, and in other cases only if it comes from the mother.

- Some sort of 'mark' must persist through the generations to tell the offspring's cells which genes to re-imprint. Whatever the precise mechanism by which they operate, the existence of imprinted genes demonstrates that not all genes are wiped totally clean of their epigenetic marks.

(Based on Ceci & Williams, 1999; Vines, 1998)

What do we mean by 'nurture'?

ASK YOURSELF...

- What do you understand by the term 'environment'?
- Try to identify different uses of the term and different 'levels' at which the environment exists.

When the term 'environment' is used in a psychological context, it usually refers to all those *post-natal* influences (or potential sources of influence) lying *outside/external* to the individual's body. These include other people, both members of the immediate family and other members of society, opportunities for intellectual stimulation, and the physical circumstances of the individual's life ('environs' or 'surroundings'). These influences are implicitly seen as impinging on a passive individual, who is *shaped* by them.

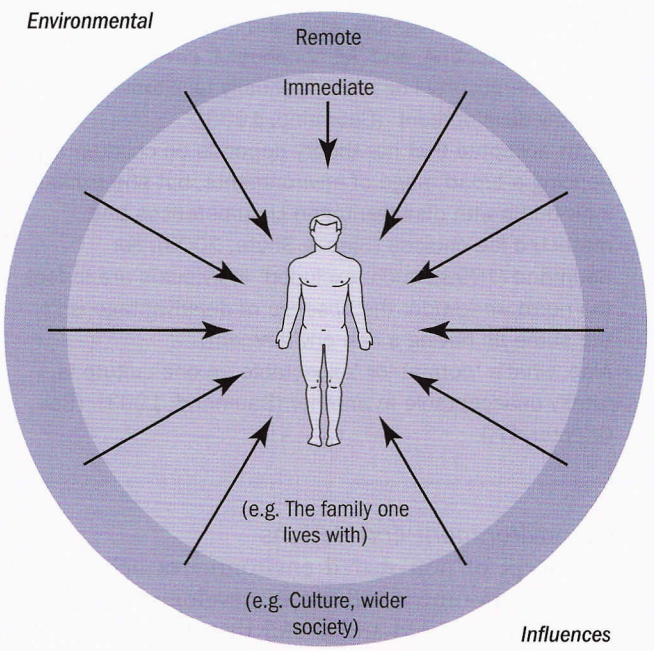

Figure 50.4 Traditional, extreme behaviourist/environmentalist view of the environment as a set of external, post-natal influences acting upon a purely passive individual

On all three counts, this view of the environment seems inadequate. It isn't just the individual person who's 'immersed in' or influenced by his/her environment, but during mitosis the specific location of any particular cell is constantly changing as the cluster of cells of which it's a part constantly grows. At an even more micro-level, the cell nucleus (which contains the DNA) has as its environment the cytoplasm of the cell.

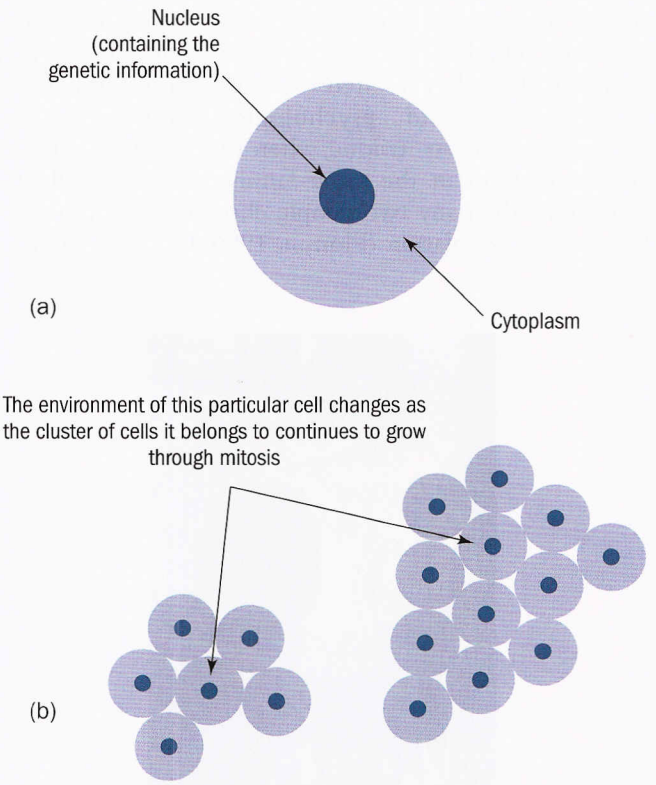

Figure 50.5 For the nucleus of an individual cell, the environment is the surrounding cytoplasm (a). The specific location of any particular cell is constantly changing during mitosis (b)

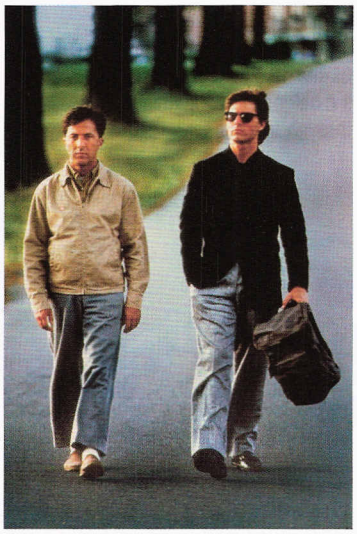


As we noted in Chapter 41, pre-natal non-genetic factors (such as the mother's excessive alcohol consumption during pregnancy) account for the largest proportion of biologically caused learning difficulties and lowered IQ. Finally, and most significantly, not only is 'nature' and 'nurture' a false dichotomy (see *Conclusions*), but it's invalid to regard the environment as existing independently of the individual (that is, objectively). Not only do people's environments influence them, but people make their own environments (Scarr, 1992: see Box 50.4). A way of thinking about how people do this is through the concept of *non-shared environments,* which is, in turn, related to *gene–environment correlation.*

Shared and non-shared environments

When the environment is discussed as a set of (potential) influences that impinge on the individual, it's often broken down into factors such as overcrowding, poverty,

socio-economic status (SES), family break-up, marital discord, and so on. In studies of intelligence, for example, children are often compared in terms of these environmental factors: children from low SES groups are commonly found to have lower IQs than those from high SES groups (see Chapter 41).

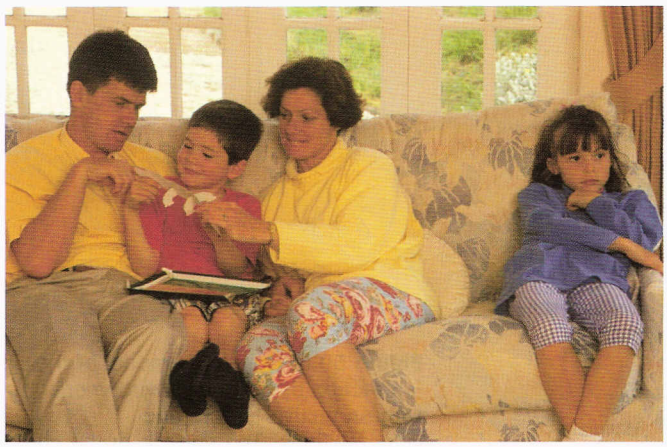
When families are compared in this way, it's assumed that children from the same family will all be similarly and equally affected by those environmental factors (*shared environment*). But for the majority of characteristics, most children within the same family aren't very similar. In fact, they're often extremely varied in personality, abilities and psychological disorders. This observation is most striking when two adopted children are brought up in the same family: they're usually no more alike than any two people chosen at random from the general population (Plomin, 1996; Rutter & Rutter, 1992).

Dustin Hoffman as the autistic brother of Tom Cruise in *Rain Man*. Both genetic and non-shared environmental factors are likely to have contributed to their different characteristics and abilities

This substantial within-family variation *doesn't* mean that family environment is unimportant. Rather, as Plomin (1996) puts it:

> Environmental influences in development are doled out on an individual-by-individual basis rather than on a family by-family basis.

In other words, differences between children growing up together is exactly what we'd expect to find, because it's the *non-shared environment* which has greater influence on development than the shared environment. Different children in the same family have different experiences. For example, Dunn & Plomin (1990) found that the ways in which parents respond differently to their different children (*relative differences*) are likely to be much more influential than the overall characteristics of the family (*absolute differences*). So, it may matter very little whether children are brought up in a home that's less loving or more punitive than average, whereas it may matter considerably that one child receives less affection or more punishment than his/her sibling. These findings imply that:



> ... the unit of environmental transmission is not the family, but rather micro-environments within families ... (Plomin & Thompson, 1987)

CRITICAL DISCUSSION 50.2 Are shared environments really that unimportant?

- Scarr (1992) acknowledges the influence of the environment on behaviour, but claims that, in reality, the environment is very similar for many individuals.
- According to the 'average expectable environment', assuming a 'normal' environment, genes will express their potential. Environmental variations within the normal range are functionally equivalent. So, provided the environment is 'normal', environmental changes (such as extra stimulation as provided by early enrichment programmes: see Chapter 41) will have no effect. Only if the environment is outside the range of normality (such as in abusive families), will such change significantly alter behavioural outcomes.
- Scarr's theory implies that children could be reassigned to and brought up by different families, without significantly affecting how they turn out. For example, differences in *parenting style* make little difference, provided the parents are 'good enough'.
- But Scarr doesn't specify what she means by 'good enough' parenting, and 'All nonabusive environments above the poverty line are not equally facilitative of healthy development' (Baumrind, 1993).
- Scarr accepted that her theory depends on children experiencing a broad range of environments, but she excluded individuals with disadvantaged circumstances and restricted life choices (Slee & Shute, 2003). For Baumrind (1993), such 'excluded' individuals are in fact the norm worldwide: the *absence* of disadvantage *isn't* the same as having a rich environment.
- Also, what's 'normal 'or 'expectable' in one culture is totally unacceptable in another (Baumrind, 1993). (See Chapter 47.)

Gene–environment correlations

The concept of non-shared environments helps explain how the environment influences development, which is far more sophisticated and useful than the original 'Is it nature or nurture?' question (see above). However, we need to understand the processes by which non-shared environments arise: why do parents treat their different children differently, and how do children in the same

Differences *within* the same family may be more important than those *between* different families

family come to have different experiences? In trying to answer these questions, psychologists and behaviour geneticists (see page 911) have, paradoxically, stressed the role of *genetic differences*. A major example of this approach is the concept of *gene–environment correlation*.

Box 50.4 Gene–environment correlations

Plomin *et al.* (1977) identified three types of gene–environment correlation.

- **Passive gene–environment correlations:** Children passively inherit from their parents environments that are correlated with their genetic tendencies. For example, parents of above-average IQ are likely to provide a more intellectually stimulating environment than lower-IQ parents.
- **Reactive gene–environment correlations:** Children's experiences derive from the reactions of other people to the children's genetic tendencies. For example, babies with a sunny, easy-going and cheerful disposition/temperament are more likely to elicit friendly reactions from others than miserable or 'difficult' babies (see Key Study 50.1). It's widely accepted that some children are easier to love (Rutter & Rutter, 1992).
- **Active gene–environment correlations:** Children construct and reconstruct experiences consistent with their genetic tendencies. Trying to define the environment independently of the person is futile, since every person's experience is different. According to Plomin (1994):

  Socially, as well as cognitively, children select, modify and even create their experiences. Children select environments that are rewarding or at least comfortable, niche-picking. Children modify their environments by setting the background tone for interactions, by initiating behaviour, and by altering the impact of environments ... they can create environments with their own propensities, niche-building.

Gene–environment interactions

The link between the concepts of gene–environment correlations and non-shared environments helps to explain how the environment exerts its influence. Another way of considering the environment's impact is to identify examples of *gene–environment interactions*.

Genetically speaking, *phenylketonuria* (PKU) is a simple characteristic. It's a bodily disorder caused by the inheritance of a single recessive gene from each parent. Normally, the body produces the amino acid phenylalanine hydroxylase, which converts phenylalanine (a substance found in many foods, particularly dairy products) into tyrosine. But in the presence of the two recessive PKU genes, this process fails and phenylalanine builds up in the blood, depressing the levels of other amino acids. Consequently, the developing nervous system is deprived of essential nutrients, leading to severe mental retardation and, without intervention, eventually leading to death (see Chapter 40).

The relationship between what the child inherits (the two PKU genes – the *genotype*) and the actual signs and symptoms of the disease (high levels of phenylalanine in the blood, and mental retardation – the *phenotype*) appears to be straightforward, direct, and inevitable: given the genotype, the phenotype will occur. However, a routine blood test soon after birth can detect the presence of the PKU genes, and an affected baby will be put on a low-phenylalanine diet. This prevents the disease from developing. In other words, an environmental intervention will prevent the phenotype from occurring. According to Jones (1993):

> [The] nature [of children born with PKU genes] has been determined by careful nurturing and there is no simple answer to the question of whether their genes or their environment is more important to their well-being.

ASK YOURSELF...

- Try to identify some examples of gene–environment interactions that involve behaviour, as distinct from bodily diseases such as PKU. Two relevant areas are intelligence (Chapter 41) and schizophrenia (Chapter 44).

If there's no one-to-one relationship between genotype and phenotype in the case of PKU, it's highly likely that there'll be an even more complex interaction in the case of intelligence, certain mental disorders, personality, and so on. One such example is *cumulative deficit*, which was discussed in Chapter 41 (see page 726). Another is the concept of *facilitativeness*.

According to Horowitz (1987, 1990), a highly *facilitative* environment is one in which the child has loving and responsive parents, and is provided with a rich array of stimulation. When different levels of facilitativeness are combined with a child's initial *vulnerabilities/susceptibilities*, there's an interaction effect. For example, a *resilient* child (one with many protective factors and a

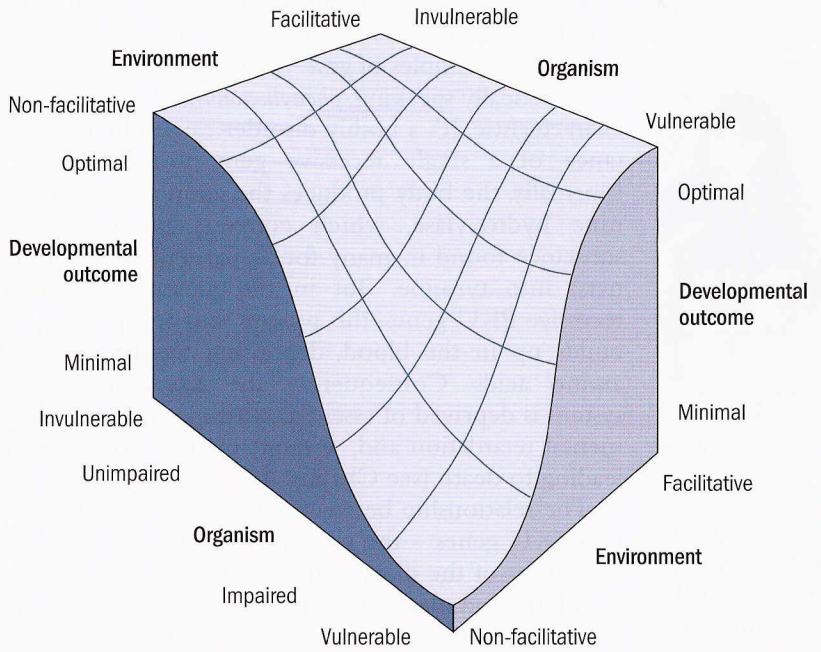


Figure 50.6 Horowitz's model of the interaction of a child's environment with protective factors and vulnerabilities. The surface of the curve illustrates the level of a developmental stage, such as IQ or social skills. According to this model, if a low-birthweight child is reared in a poor environment, then it's likely that child will do less well than other children reared with a different combination of vulnerabilities and environment

few vulnerabilities) may do quite well in a poor environment. Equally, a *non-resilient* child may do quite well in a highly facilitative environment. Only the *non-resilient* child in a *poor* environment will do really poorly (see Figure 50.6).

This interactionist view is supported by a 30-year longitudinal study that took place on the Hawaiian island of Kanuai.

KEY STUDY 50.1 Werner's 'Children of the Garden Island'

- Starting in 1955, Werner and her colleagues studied all of the nearly 700 children born on Kanuai in a given period, and followed them up at the ages of 2, 10, 18 and 31–32.
- Werner became interested in 72 'high risk'/'vulnerable' children. They'd been exposed before the age of two to 4 or more of the following risk factors: reproductive stress (either difficulties during pregnancy and/or during labour and delivery), and discordant and impoverished home lives (including divorce, uneducated, alcoholic or mentally disturbed parents).
- Despite their early exposure to these risk factors, these children went on to develop healthy personalities, stable careers and strong interpersonal relationships.
- As babies, these resilient children were typically described as 'active' 'affectionate', 'cuddly', 'easy-going' and 'even-tempered', with no eating or sleeping habits causing distress to their carers. These are all temperamental characteristics that elicit positive responses from both family members and strangers.
- There were also environmental differences between the resilient and non-resilient children, such as smaller family size, at least two years between themselves and the next child, and a close attachment to at least one carer (relative or regular baby-sitter). They also received considerable emotional support from outside the family, were popular with their peers, and had at least one close friend. School became a refuge from a disordered household.
- Sixty-two of the resilient children were studied after reaching their thirties. As a group, they seemed to be coping well with the demands of adult life. A total of 75 per cent had received some college education, nearly all had full-time jobs and were satisfied with their work. According to Werner (1989):

  As long as the balance between stressful life events and protective factors is favourable, successful adaptation is possible. When stressful events outweigh the protective factors, however, even the most resilient child can have problems.

ASK YOURSELF...

- In what ways can culture be thought of as an environmental influence on an individual's behaviour?
- Try to identify examples from different areas of psychology, but Chapter 47 might be a good place to begin.

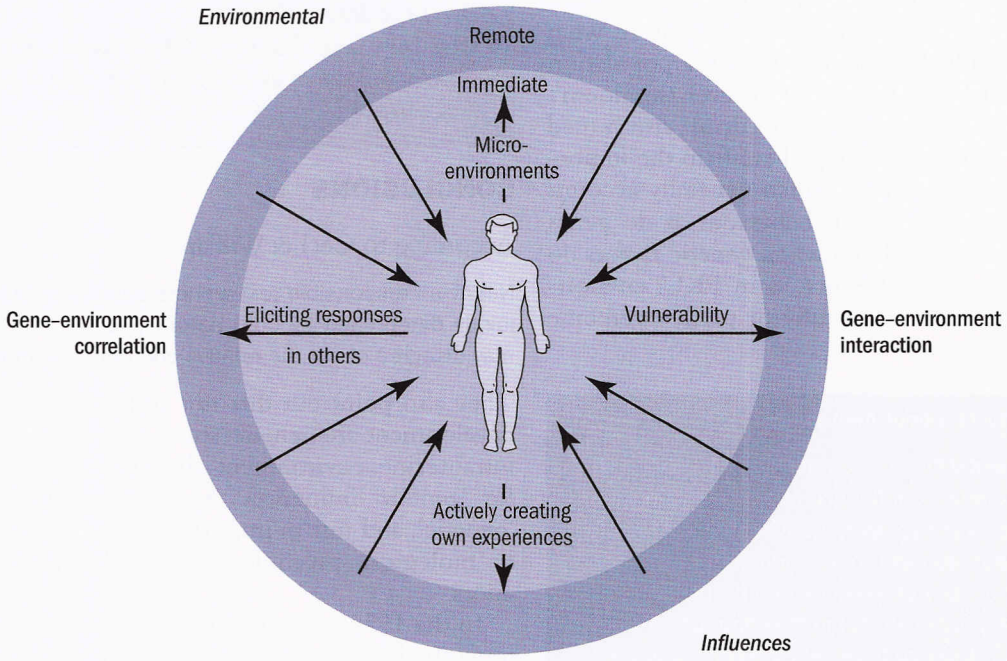

Figure 50.7 The post-natal, sociocultural environment, with the individual portrayed as actively influencing the environment as much as s/he is influenced by it

Behaviour genetics and heritability

Behaviour genetics

According to Pike & Plomin (1999), 'Behaviour geneticists explore the origins of individual differences ... in complex behaviours'. More specifically, they attempt to quantify how much of the variability for any given trait (such as intelligence, aggressiveness, or schizophrenia) can be attributed to (a) genetic differences between people (*heritability*), (b) *shared environments,* and (c) *non-shared environments.* The heritability of intelligence was discussed in Chapter 41, as were the two major methods used by behaviour genetics, namely twin studies and adoption studies (also see Chapter 44).

If genetic factors are important for a trait, identical twins (MZs) will be more similar than non-identical twins (DZs). To the extent that twin similarity cannot be attributed to genetic factors, the *shared environment* is implicated. To the extent that MZs differ within pairs, *non-shared environmental factors* are implicated. Because adopted siblings are genetically unrelated to their adoptive family members, the degree of similarity between them is a direct measure of *shared environmental influence* (Pike & Plomin, 1999).

One interesting finding from behaviour genetic research is that the effects of a shared environment seem to *decrease* over time. In a 10-year longitudinal study of over 200 pairs of adoptive siblings, Loehlin *et al.* (1988) found that at an average age of eight, the correlation for IQ was 0.26. This is similar to other studies of young adoptive siblings, and suggests that shared environment makes an important contribution at this age. However, by age 18 the correlation was close to zero. According to Pike & Plomin (1999):

> These results represent a dramatic example of the importance of genetic research for understanding the environment. Shared environment is important for [general intelligence] during childhood when children are living at home. However, its importance fades in adolescence as influences outside the family become more salient.

This conclusion might at first appear paradoxical, yet behaviour genetics provides the best available evidence for the importance of *nongenetic* factors in behavioural development (Plomin, 1995). For example, the concordance rate of MZs for schizophrenia is 40 per cent, which means that most pairs are discordant for diagnosed schizophrenia (see Chapter 44). While there can be no genetic explanation for this, 20 years ago the message from behaviour genetics research was that genetic factors play the major role. Today, the message is that these same data provide strong evidence for the importance of environmental factors as well as genetic factors (Plomin, 1995). Additionally, the data from twin studies are open to interpretation because not all MZs are equally identical. This is due to certain critical *pre-natal environmental* factors (Ceci & Williams, 1999).

Heritability

According to Ceci & Williams (1999), *heritability* is one of the most controversial concepts in psychology. As noted

earlier, it's a statistical measure of the genetic contribution to differences between individuals, that is, it tells us what proportion of individual differences within a population (*variance*) can be attributed to genes. However, this doesn't mean that 'biology is destiny'. Indeed, as also noted above, behaviour genetics has helped confirm the importance of environmental factors, which generally account for as much variance in human behaviour as do genes (Plomin & DeFries, 1998). Even when genetic factors do have an especially powerful effect, as in PKU, environmental interventions can often fully or partly overcome the genetic 'determinants'.

Box 50.5 Some 'facts' about heritability

- The degree of heritability (or *heritability estimate*/h^2) isn't set in stone: the relative influence of genes and environment can change. For example, if environmental factors were made almost identical for all members of a hypothetical population, any differences in a particular characteristic (say, intelligence) in that population would then have to be attributed to genetics. Heritability would be closer to 100 per cent than 50 per cent.
- At the same time, however, equating the environment would probably reduce the size of differences observed among individuals. If all children enjoyed the best environment possible, they'd probably differ much less than if some had been given the worst possible environment.
- Within the *same* population, h^2 will differ depending on which trait is being measured (for example, it's higher for IQ than for most aspects of personality: see Chapter 42).
- h^2 will also differ for the same trait when assessed in *different* populations.
- h^2 will tend to be higher in a good environment than a poor one; the former provides the necessary resources for the biological potential to be realised.
- h^2 is a way of explaining what makes *people different*, not the relative contribution of genes and environment to any *individual's* make-up.
- The explanation of individual differences *within* groups bears no relation to the explanation of differences *between* groups (see Chapter 41).
- Traits that are *universal* (such as the capacity for language) have *zero heritability*, but are clearly *inherited*. This point is often overlooked even in texts about the nature–nurture debate (Wells, 2000).

(Based on Ceci & Williams, 1999; Plomin & DeFries, 1998)

According to Ceci & Williams (1999):

> Heritability estimates are highly situational: they are descriptions of the relative contributions of genes and environments to the expression of a trait in a specific group, place and time. Such estimates tell us nothing about the relative contributions if the group, place or time is changed.

ASK YOURSELF...

- Based on your reading of this chapter, what conclusions would you draw about the influence of nature and nurture?

CONCLUSIONS

According to Ceci & Williams (1999):

> Nearly all responsible researchers agree that human traits are jointly determined by both nature and nurture, although they may disagree about the relative contributions of each.

They also point out that not all biological influences on development are genetic: some are critical features of the intrauterine environment that are sometimes mistaken for genetic influences. So, 'biological' doesn't mean 'genetic', and just as importantly, 'environment' can refer to biological, psychological, social, and cultural influences.

In the 1950s, the extreme environmentalism of behaviourism dominated thinking about nature–nurture, but the 1960s saw the adoption of a more balanced view. The 1980s and 1990s saw psychology becoming much more accepting of genetic influence (Plomin, 1996). Plomin (1995) maintains that:

> Research and theory in genetics (nature) and in environment (nurture) are beginning to converge ... the common ground is a model of active organism–environment interaction in which nature and nurture play a duet rather than one directing the performance of the other ... It is time to put the nature–nurture controversy behind us and to bring nature and nurture together in the study of development in order to understand the processes by which genotypes become phenotypes.

Similarly, Ceci & Williams (1999) conclude like this:

> The battle today seems more over the specific genetic and environmental mechanisms than over whether genes or environments matter.

CHAPTER SUMMARY

- The **nature–nurture debate** concerns fundamental questions about the causes of human behaviour, sometimes focusing on behaviours and abilities **shared by all human beings**, and sometimes on **individual differences**.
- **Nativists** see knowledge of the world as largely innate, while **empiricists** stress the role of learning and experience. These extreme viewpoints are reflected in early psychological theories, such as Gesell's **maturation** and Watson's **behaviourism**, respectively.
- The concept of maturation continues to be influential in psychology, as in biological processes such as puberty and ageing, and stage theories of development. Watson's

environmentalism was adopted in Skinner's **radical behaviourism**.

- Nativism and empiricism aren't mutually exclusive. Not only must the environment be **benign**, but particular environmental input is often necessary. In both Freud's and Piaget's theories, experience is just as important as the underlying maturation. Both are **interactionists**.
- **Genetics** is the science of heredity. **Genes** are the basic units of hereditary transmission, responsible for **self-duplication** and **protein synthesis**. Self-duplication occurs through **mitosis** (in the case of non-reproductive cells) and **meiosis** (in the case of reproductive cells).
- **Neurogenetic determinism** makes the false assumption that causes can be classified as *either* genetic *or* environmental. Also, the phrase 'genes for' is a convenient but misleading shorthand for complex biochemical processes.
- Cells inherit genes along with an 'epigenetic' instruction manual, without which multicellular organisms would be impossible. Changes in the instruction manual may be passed from parent to offspring. Heredity may thus involve more than DNA.
- The term '**environment**' is commonly used to refer to **postnatal** influences lying **outside** the body of a passive individual who's shaped by them. However, people also make their own environments, and for most characteristics, the **shared environment** seems to have little impact on development compared with the **non-shared environment**.
- The concept of non-shared environments helps explain how the environment influences development. Two ways in which non-shared environments arise are **gene–environment correlations** and **gene–environment interactions**.
- PKU illustrates the lack of a one-to-one relationship between **genotype** and **phenotype**. Other examples include **cumulative deficit** and Horowitz's concept of **facilitativeness**.
- **Behaviour genetics** attempts to quantify how much of the **variability** for any particular trait is due to **heritability**, shared environments, and non-shared environments.
- **Heritability estimates** describe the relative contributions of genes and environment for particular traits, in a specific population, at a particular place and time. They are measures of individual differences **within** groups, and can tell us nothing about **between**-group differences or particular individuals within a group.
- Human traits are determined by **both** nature and nurture. Where researchers may still disagree is over the **relative contributions** of each, and the specific genetic and environmental **mechanisms** involved.

Links with other topics/chapters

- Phenylketonuria (PKU) is a much-cited example of how genetic factors don't inevitably result in particular behaviours/abilities (phenotypes), which is especially relevant to discussion of individual differences in *intelligence* (Chapter 41).
- Neurogenetic determinism is one of four major kinds of *determinism* identified by Rose (Chapter 49, Box 49.6).
- The epigenetic principle is an important feature of Erikson's *psychosocial theory of development* (Chapters 37–39).
- According to Claridge & Davis (2003), the reason for taking an interest in the genetic effects on individual differences (and there's good evidence they exist) *isn't* to *reduce* everything to heredity, but to see where such influences fit into the larger picture about personality (Chapters 42 and 49).
- According to Joseph (2003), in the MGR literature it's striking how little attention is paid to people's social environment as a cause of 'mental illness'. The causes are viewed as residing at the molecular level. This epitomises the *reductionist* view of human problems (Chapter 49) and also illustrates *individualism* (Chapter 47).
- An example of reactive gene–environment correlation is the observation that *aggressive children* tend to experience *aggressive environments* because they tend to evoke *aggressive responses* in others (Chapter 29).

SUBJECT INDEX

abnormality
  as deviation from the norm 758–59, 762
  as distress 760
  and dreaming 119
  and free will 889–90
  as maladaptiveness 760
  as mental illness 761–64
  as predictable/unpredictable behaviour 760–61
academic psychology 7
accommodation
  in cognitive develoment 582, 583
  in vision 80, 81, 248
acculturation 189
acetylcholine 58
achievement motivation 153
action potential 56–57
action slips 228–29
activation-synthesis model (dreaming) 120–21
activity (re-engagement) theory (old age) 673
actor-observer effect (AOE) 402, 734
adaptation
  to environment 576
  and motivation 151
  visual 83, 266, 269–70
addiction 124–26, 135–36
adipsia 148
adolescence
  and delinquent behaviour 640, 642, 836–38, 841
  and drugs 642
  focal theory of (Coleman) 646
  identity crisis theory of (Erikson) 640–44
  identity status theory of (Marcia) 644
  and initiation rituals 641, 642–43
  and mental disorder 639–40
  multiple transitions in 636
  and normative/non-normative shifts 636, 637, 646
  and peer relationships 563, 645
  perpetual 651
  and puberty 636–39
  risk-taking behaviour in 641–42
  and sex 637
  sociological approaches to 643–45
  storm and stress theory of (Hall) 639–40
  and time of maturing 638–39
adoption studies
  and intelligence tests 721–22
  late adoption 556, 557–59
  and schizophrenia 798
adrenaline 162, 163–64
adrenals 73, 75
adrenocorticitrophic hormone (ACTH) 206
adult attachment interview (AAI) 560
adulthood
  adult consciousness, evolution of (Gould) 656
  changing sense of time in 656
  normative/non-normative influences 649, 656
  psychosocial stages (Erikson) 649–51, 655
  seasons of a man's life (Levinson et al.) 651–55
advertising 416–17
aerobic exercise 195
affectionless psychopathy 555–56
affective primacy 167, 168
affiliation 154
affordances 257–58
age, and crime 836–37
ageism 425, 668–69
aggression
  aggressive-cue theory (ACT) of 495, 499–500
  and antisocial behaviours 495
  appeasement rituals in 496
  attribution of 495, 498, 499
  Bobo doll experiments 501–02, 616
  definitions of 495
  and deindividuation 506–08
  ethological theory of (Lorenz) 495–97
  excitation-transfer theory of (Zillman) 501
  frustration-aggression hypothesis of (Dollard et al.) 495, 498–99
  and intention 495, 498
  and media violence 502–06, 523
  psychoanalytic approach to (Freud) 495, 497–98
  and sexual differences 625
  social constructionist approach to 508–09
  social learning theory of (Bandura) 501–02
  and threat displays 159
agoraphobia 777
AIDS/HIV 133, 187, 193–95, 414–15
alarm reaction (stress) 204, 205
alcohol
  consumption 130–31
  dependence 135–37
  effects of 129–30
  and memory 130
  safe levels for 129
  and sex 130
Alcohol dependence syndrome (ADS) 136
Alcoholics Anonymous 135, 136–37
alertness 106
algorithms 341
alpha rhythms 110, 129
alpha waves 111, 115
altruism
  biological 522–23
  and bystander intervention 512–18
  empathy-altruism hypothesis (EAH) 521–22
  paradox of 522, 527
  and universal egoism 512
Alzheimer's disease 239, 670–72
American Psychological Association (APA) 39, 860, 868–69, 873
Ames' distorted room 258–59, 277
amnesia
  anterograde 289–90
  and dreaming 119
  and repression 367
  retrograde 290
amnesic syndrome 290
amphetimines 131–32
amygdala 126, 843
anal stage (psychosexual development) 603
analogical thinking 345
analogy 13, 26
analytical psychology (Jung) 21, 752–54
androcentrism 47, 612, 858–61
androgen insensitivity syndrome (AIS) 623
androgenital syndrome (AGS) 623
animal experiments
  animal suffering, judging 877–78
  and comparative psychology 6–7
  justifications for 878, 879–81
  safeguards in 878–79
  of visual perception 265, 267–69
animism 585
anorexia nervosa (AN) 148, 800–02, 803–05
antecedent variables 38
anti-essentialism 28
antidepressant drugs 811–12
antipsychiatry movement 799
antipsychotic drugs 813
antisemitism 427–28, 429
antisocial behaviour 495, 523–24
antisocial personality disorder (APD) (psychopathy) 842–45
anxiety disorders 776–84
anxiolytic drugs 739, 813
aphagia 145
aphasia 59, 69
appetite control system 143
applied psychology 8–12
archetypes 753
army alpha and beta tests (intelligence) 713
arousal 106, 117, 152–53, 161, 163–67, 225, 505
arousal-cost-reward (ACR) model
  arousal 516
  cost-reward analysis 516–18
  gender differences 520
  helping, types of 518
  personality differences 519
  universal egoism 520, 522
  victim differences 518–19
  we-ness 520
articulatory/phonological loop (working memory) 293, 294
artificial intelligence (AI)
  computers, and brains 349–53
  definitions of 348–49
  expert systems 344–45
  and problem-solving 339

strong and weak 350–51
artificiality (in experiments) 47
ascending reticular activating system (ARAS) 67, 738–39
Asch paradigm 444
Asperger's syndrome 690
assimilation (in cognitive development) 582, 583
association areas, in cortex 65–66
associative learning 18
attachment
behaviourist view of 543
Bowlby's theory of 545–47
cultural differences in 547, 550
cupboard love theories of 543–44
definition of 542
and deprivation 552–59
and early adult transition 652
ethological theory of 544
and imprinting 545
and institutional care 551, 557–58
and intergenerational continuity 559–60
and internal working models (IWMs) 559, 561
and later relationships 559–62
and love 476–77
maternal-deprivation hypothesis (MDH) (Bowlby) 551–49
minimal parenting 561–62
phases in development of 542–43
psychoanalytic accounts of 543
and sibling relationships 562–64
and sociability 542
and Strange Situation 547–51
attention
attenuation model of (Treisman) 219, 220
central capacity interference theory of 225–26
definitions of 216
divided attention 216, 224–29
early selection filter theory (Broadbent) 218–19
focused auditory attention 217–21
focused visual attention 221–24
information-processing approach 216
late selection filter model of (Deutsch-Norman) 220
selective attention 216–17, 224
working memory (WM) model 282, 292–93, 599
attitude change
cognitive dissonance theory (CDT) of 406, 418–20, 420–21
and cultural factors 420–21
self-perception theory (SPT) of 420–21
attitudes
and behaviour 409–10
definitions of 406
functions of 407, 413
measurement of 408–09
and persuasion 406, 413
propaganda 406
and social cognition 406, 411
and social influence 411–18
three-component model of 406–07
and values 406
attraction, interpersonal *see* interpersonal attraction
attribution 375, 378
and aggression 495, 498, 499
and commonsense psychology (Heider) 395–96
configuration model of (Kelley) 399–400
correspondent inference theory (CIT) of (Jones & Davis) 396–98
covariation model of (Kelley) 398–400
and depression 789
dispositional factors 395, 396–98, 420
of emotion and motivation (Weiner) 400–401
error and bias in 401–04
and naïve scientist 395–96
situational factors in 395, 403
atypical development 8
authoritarian personality 427–30, 435
authority, in obedience studies 461, 462–63
autism
behavioural approaches to 695
biological approaches to 695
cognitive approaches to 696
definition of 689–90
diagnosis of 690
and Down's syndrome 683, 685, 691–92
and impaired executive functioning 695
incidence of 690
and operant conditioning 823
and savant syndrome 685–88
theories of 692–96
and theory of mind 199, 691, 693–95
treating 696–97
and weak central coherence 694–95
autistic spectrum 690
autobiographical memory 291, 577
autokinetic effect 252, 442
autonomic nervous system (ANS) 55, 72–73, 80, 739
and amphetamine use 131–32
and emotions 76, 158, 161, 162, 163
and stress 204, 205, 206
autonomous morality (Piaget) 605, 606
average evoked potentials (AEPs) 60–61, 110
averaged effect size 99
aversion therapy 821–22
avoidance learning 179
axons 54–55, 56, 57

babbling 322
babies
and face recognition 273
perceptual abilities of 265, 270–76
balance theory (Heider) 418, 481
basal ganglia 66–67, 781–82
base rate fallacy 346, 347
beauty, sociobiology of 483–84
behaviour modification 10, 18, 35, 418, 823–25, 882
behaviour therapy 10, 18, 820–22
behavioural blindness 268–69
behavioural medicine 187
behavioural neuroscience 18
behavioural pharmacology 18
behavioural rehearsal 119
behaviourism
basic principles of 17–18
cognitive 18, 26, 150
evaluation of 18–19
methodological 17
and motivation 140
and objectivity 105
as paradigm 43
practical contributions of 18
and problem-solving 340
radical 17, 19, 39, 892, 893, 897, 902
theoretical contributions of 18
and thought–language relationship 307
see also learning
behaviourist manifesto (Watson) 4, 17, 39, 901
bereavement 677–80
beta waves 111, 115
bias
and attribution 401–04
cultural 612, 861–65
decision-making heuristics 346–47
and error 401–04
gender 612–13, 839–40, 856–61, 861
big five (personality factors) 742–43
bilateral representation 69

  and immune system 206–08
  life changes, and SSRS 203
  models of 200–201
  moderator variables in 208–09
  occupational 204
stress management 210
striate cortex 84–86
stroboscopic motion 252
strokes 59, 69, 87, 131
Stroop effect 227
structuralism 4, 38, 43
structure of intellect model (intelligence) (Guilford) 708, 709
subjectivity 4, 23, 105
subjects, participants as 47, 49
subliminal perception 167, 417–18
substance abuse
  defining 124–28
  drugs of abuse 123–24, 128
subtle prejudice 434–35
suggestibility 362–63
suicide 785, 844–45
superego 602, 603, 604, 817
superstition hypothesis 780
suprachiasmatic nucleus (SCN) 111–12
symbolic interactionism, and self 570–71
symbolic mode, of representation (Bruner) 597
sympathetic branch (autonomic nervous system) 72–73
synaesthesia 87–88, 134
synapses 54, 56, 57
synaptic transmission 55–56, 62
syncretic thought 585
syntax 321
systematic desensitisation 22, 175, 820–21, 883

talent 688–90
task analysis 598
taste aversion studies 146
teaching *see* education
teaching machines 18
technological addictions 125
telegraphic speech 323
telepathy 94, 95, 97
testosterone 130, 622, 624, 654
tetrachromatic theory (colour vision) 89
thalamus 66, 160, 163
thematic apperception test (TAT) 153
theory construction 13, 41
theory of mind 199, 589, 691, 693–94
theory of planned behaviour (TPB) 411
theory of reasoned action (TRA) 410
therapies
  behavioural aproaches 819–25

biological therapies 810–17
client-centred therapy (CCT) 828–30
cognitive-behaviour therapy 825–28
electroconvulsive therapy 813–15
and outcome research 829–32
and process research 831–33
psychoanalysis 817–19
psychosurgery 815–16
psychotherapy 809
thirst *see* drinking
Thorndike's puzzle box 18, 176
thought, and language 306–17
thought-action fusion (TAF) 781
threat displays 159
threat simulation theory 121
thymus 74
thyroid 74
tip-of-the-tongue (TOT) phenomenon 240, 301
token economy (TE) 823–25, 883
tolerance, of drugs 126, 127, 131, 132, 133, 134
tonic alertness 106
Tourette's disorder 781, 887
traits *see* personality
tranquillisers 128
transactional analysis (TA) (Berne) 22
transactional model of stress 200–201, 209
transactionalism 258
transcultural psychology 28–29
transductive reasoning 585
transfer of learning (training) 184
transference 23, 817–18
transformational grammar 327–28
transitivity 587
treatments, classification of 808–10
trial-and-error learning 176
triarchic theory of intelligence (Sternberg) 710–11
tricyclics 811
Turing test 350–51
turn-taking 330
twin studies 315
and intelligence 720–21
and schizophrenia 793, 796, 797
two-factor theory (intelligence) (Spearman) 707
Type A Behaviour Pattern (TAPB) 208
type theory of personality (Eysenck) 737–41, 742

ultradian ryythm 106, 114–15
unconditioned response 172–73
unconditioned stimulus 172–75, 182
unconscious 19, 23, 105, 748, 752–54
unfalsifiability problem 22, 33, 118, 750
unilateral visual neglect 238–39
unipolar depressive disorder (UDD) 785–91
universal egoism (and helping behaviour) 512, 520, 522
universalist assumption 28–29

vagus nerve 144, 147
validity 47–48, 771
variables 47–48
ventral tegmenal area (VTA) 126
ventrobasal complex 66
ventromedial hypothalamus (VMH) 144, 147–48
violence 497–498, 502, 506, 523
visual cliff apparatus 274
visual co-orientation (joint attention) 330
visual cortex 84–87
visual illusions 277
visual pathways (eye to brain) 84–88
visual perception
adaptation/readjustment, studies of 266, 269–70
animal experiments of 265, 267–69
in babies 270–76
classifying theories of 254
computational theory of (Marr) 260–62
connectionist models of 262
constructivist theory of (Gregory) 254–57, 259
cross-cultural studies of 266, 277–78
deficits 699
direct perception theory of (Gibson) 257–59
in human catatact patients 265–67
methods of studying 270–71
nature–nurture debate in 265, 266, 279
visual system 80–88, 253–54
visually evoked potentials (VEPs) 271
visuospatial scratch pad (working memory) 293
vitreous humour 81, 82
volume transmission 56
voluntary behaviour 888–89

Weber-Fechner law 80
Wernicke's area 59, 64, 68
will to power 21
wish fulfilment 121
withdrawal 127, 131, 133, 134
women
and crime 838–39
and employment 660–61
working memory (WM) 282, 292–93, 599

Zener cards 95–96
zone of proximal development (ZPD) 594, 595
